The questions that remain have been well defined (*13*). A high-priority question is whether repetitive screening with physical examination tied to instruction in breast self-examination achieves most of the effects found in screening that also utilizes mammography. Reduced costs for screening and elimination of radiation exposure, although very low under controlled conditions, are the issues at stake. At the same time, improvement in early case detection among women under age 50 and among older women through modern mammography has been demonstrated (*13*). This fact raises the possibility that under present conditions, screening would have a beneficial effect under age 50. Resolution of the issues of relative value of palpation alone versus palpation and mammography and the efficacy of screening under age 50 has such great consequences for the spread of breast cancer screening to merit new investments in appropriately designed randomized trials. Fortunately, a move in this direction has already been taken by the National Cancer Institute of Canada (*14*).

Antigenic Heterogeneity of Human Colorectal Cancer Cell Lines Analyzed by a Panel of Monoclonal Antibodies. I. Heterogeneous Expression of Ia-Like and HLA-Like Antigenic Determinants[1,2]

Grant D. MacLean,[3,4] Jutta Seehafer,[4] Andrew R. E. Shaw,[4] Mark W. Kieran,[3] *and* B. Michael Longenecker[3,5,6,7]

ABSTRACT—The pattern of reactivity of 10 monoclonal antibodies (MCA) developed against human lymphoid leukemia cells and tested with human T-cells, B-cells, as well as T-lymphoma and B-lymphoma cell lines suggested that six of them detect Ia-like determinants, three detect HLA-like determinants, and the remaining one detects a non-Ia B-cell antigen. With the use of three binding assays, the six MCA that appeared to detect Ia-like determinants reacted strongly with the human colorectal cancer cell (CCC) line LoVo, and none of the three MCA that reacted with HLA-like determinants reacted with this cell line. Immunoprecipitation and polyacrylamide gel electrophoresis analysis confirmed the apparent specificities of the MCA for Ia-like and HLA molecules, demonstrated the presence of Ia-like molecules in LoVo, and failed to detect HLA in these cells. The cellular enzyme-linked immunosorbent assay was used for the testing of our anti-Ia and anti-HLA MCA with 15 other CCC lines. Marked heterogeneity was found in the expression of different Ia-like and HLA determinants defined by different or overlapping subsets of MCA, which suggested that these determinants might be present on different molecules or that different conformations of the same molecules exist in various CCC lines. Analysis of the surface phenotype of subclones of LoVo cells revealed the presence of stable variant cell subpopulations, which lost reactivity with four out of six of the anti-Ia-like MCA but retained at least one Ia-like molecule recognized by two of our MCA. All of the subclones maintained the HLA-negative phenotype. The possible immunologic and diagnostic consequences of the presence or absence of Ia-like or HLA markers on nonlymphoid tumor cells are discussed.—JNCI 1982; 69:357–364.

In recent years it has become apparent that despite their monoclonal origin many experimental tumors are comprised of subpopulations of cells of varying phenotypes (*1*). This heterogeneity of tumors has been demonstrated with respect to several traits including susceptibility to cytotoxic drugs (*2*), immunogenicity (*3*), and antigenicity (*4*). Tumors also consist of subpopulations of cells with widely differing metastatic properties. Clonal variation in metastatic potential was first demonstrated by Fidler and Kripke (*5*) using the B-16 melanoma mouse model. These workers demonstrated the existence of tumor cell population clones that differed widely in their abilities to form lung metastases, showing that the potential to form lung metastases was inherent in certain clones within the unselected tumor cell population. We have recently demonstrated clonal variation in the ability of lymphoma clones to form liver-specific metastases (*6*). Furthermore, with use of an MCA, we identified an antigenic determinant whose expression correlates with the metastatic capacity of a given clonal variant, which suggests that this molecule might have a functional role in the interaction of blood-borne, metastasizing tumor cells with a specific target organ (*6, 7*).

Little work has been done with the antigenic heterogeneity of human tumors, chiefly because of the lack of suitable probes for the detection of antigenic variants of human tumors. The unexpected expression of Ia-like antigens on human melanomas as well as various other nonlymphoid human cancers has recently been reported (*8–16*). Because the presence or absence of Ia-like and HLA antigens on solid tumors might have a profound influence on the biology of tumors and on the interaction of the tumor with the host's immune system (*17, 18*), we began an analysis of the antigenic heterogeneity of solid human tumors with a panel of 10 MCA that appear to detect HLA and Ia-like determinants. In preliminary experiments we found that one human CCC line appeared to possess the interesting and unexpected phenotype Ia^+, HLA^-. Thus we wished to extend our studies to include 15 other human CCC lines as well as individual subclones of one line to attempt the detection of tumor heterogeneity in the expression of Ia-like and HLA-like antigens. For these studies we used Leibovitz's SW series of well-characterized human colorectal tumors (*19*).

MATERIALS AND METHODS

1) *MCA nomenclature.*—All MCA were produced in our laboratories. Most have a code name that includes "H" denoting human cells were used for immunization. The negative control MCA D228b was produced against a *Neis-*

ABBREVIATIONS USED: CCC=colorectal cancer cell(s); CEA=carcinoembryonic antigen; ELISA=enzyme-linked immunosorbent assay; IF=immunofluorescence; MCA=monoclonal antibody (antibodies); PAGE=polyacrylamide gel electrophoresis; RIA=radioimmunoassay; SDS=sodium dodecyl sulfate.

seria meningitidis serotype (*20*). The nonreacting hybridoma 8H2A1 was used for production of control ascites.

2) *Immunizations.*—The H series MCA were produced after immunization of mice as follows: 7H—CLL blood leukocytes (>95% lymphocytes); 8H—cells from the Raji line (derived from Burkitt's lymphoma); 9H—CML blood leukocytes; 10H—ALL bone marrow leukocytes; 41H—spleen lymphoid cells from a patient with hairy cell leukemia (>65% "hairy cells"); and 50H—cells from the malignant melanoma cell line MEL-T-1.

3) *Fusions.*—The fusion technique is modified from that of Köhler and Milstein (*21*) and has been previously described (*22*).

4) *Cells used for specificity testing.*—*a*) Lymphocytes from peripheral blood samples from random normal human donors were separated first with Ficoll-Hypaque and then into "T"- and "B"-subsets after incubation with nylon wool. (The B-cell subfraction, comprising 50–70% cells reacting with a fluorescent goat antihuman immunoglobulin heterologous antiserum, also includes monocytes)

b) The cell lines Raji and MEL-T-1 have been passaged in our laboratories for many years. The Daudi lines (Burkitt's lymphoma derived) were provided by Dr. P. J. M. Mannoni, Blood Transfusion Services, Edmonton, Canada. CCRF-SB (B-cell type) and MOLT-4 (T-cell type), 2 acute lymphocytic leukemia-derived cell lines, were provided by Dr. J. Menezes, Hospital Sainte-Justine, Montreal, Canada.

c) LoVo, a CEA-producing human CCC line (*23, 24*) was supplied recently by Dr. Benjamin Drewinko, M. D. Anderson Hospital and Tumor Institute, Houston, Tex. The SW series of human CCC lines (*19*) were recently provided by Dr. W. B. McCombs and Dr. O. D. Holton, Scott and White Clinic, Temple, Tex. The other human CCC line, WiDR, was recently purchased from the American Type Culture Collection, Rockville, Md.

5) *Specificity testing.*—*a, b*) Testing of lymphocytes and lymphoid cell lines was by both complement-mediated cytotoxicity (at 37°C with Cedarlane Low-Tox rabbit complement; Cedarlane Laboratories, Hornby, Canada) and indirect immunofluorescence [at 4°C with fluorescein-labeled F(ab')$_2$ (Cappel Laboratories, Cochranville, Pa.) goat-antimouse immunoglobulin, and azide to prevent capping]. This testing was used to avoid missing any potentially important positive reactions. *c*) The CCC lines were tested initially by ELISA with the β-D-galactosidase system (Bethesda Research Laboratories, Inc., Gaithersburg, Md.). The cells were trypsinized (trypsin-EDTA), added at 10^5 cells per well to Nunc 96-well flat-bottom tissue culture plates (A/S Nunc, Copenhagen, Denmark), and allowed to grow over 24 hours into a confluent adherent layer. The cells were then fixed in 0.1% glutaraldehyde in 0.1 *M* $NaHCO_3$ and incubated with 10% fetal calf serum in phosphate-buffered saline (pH 7.4) for blocking of nonspecific MCA binding. The fixed, blocked tumor cells were then assayed by the ELISA method with use of β-D-galactosidase recording the optical denisty in each well with a Titertek Multiskan. Controls for nonspecific binding of MCA included myeloma proteins from all known IgG subclasses, IgM and IgA. No nonspecific binding was detected. Testing was repeated on at least 3 different days for each CCC line with consistency of results.

The LoVo line was tested by indirect immunofluorescence. A cell suspension was prepared with trypsin-EDTA plus RPMI-1640 medium (1:1) and tested as in 4*b* above.

d) Selected MCA were also intrinsically labeled with [^{35}S]methionine (*25*) for analysis by RIA of selected cell lines.

6) *MCA dilution.*—The 41H and 50H MCA were tested as neat culture supernatant with medium as negative control. The other MCA were derived from the ascites of pristane-primed mice given injections ip of the hybridomas with use of 8H2A1 as negative control ascites. These ascites-derived MCA were used at a dilution of 1:500 because our titration studies (unpublished observations) showed 1:500 to be on the plateau of the dose-response curve, well clear of the prozone often observed at high concentration, with most MCA reactive to a dilution of $1{:}10^6$.

7) *Immunoprecipitation of radiolabeled antigens.*—Cells from the Raji line and the LoVo line were intrinsically labeled with [^{3}H]leucine [2×10^6 cells pulsed with 100 μCi of [^{3}H]-leucine-55 mCi/mmol (New England Nuclear Corp., Boston, Mass.) for 5 hr]. Labeled proteins were extracted from washed cells with 0.5% sodium deoxycholate and 0.5% Nonidet P-40 in 20 m*M* Tris-HCl phosphate buffer (pH 8.0) in the presence of protease inhibitors phenol methylsulfonyl fluoride (1 m*M*) and chloromethyl L-(2-phenyl-1-*p*-toluenesulfonamido)ethyl ketone (0.5 m*M*). Lysates were sonicated and clarified by centrifugation (15,000 rotational centrifugal force) before addition of MCA-containing ascites at concentrations of 1:100–1:1,000. Antibody-bound antigens were precipitated with *Staphylococcus aureaus* protein-A bound to Sepharose CL4B (Pharmacia Fine Chemicals, Piscataway, N. J.). Precipitated complexes were solubilized in 1% SDS, 5% 2-mercaptoethanol, and separated in a 12.5% polyacrylamide slab gel in 1 m*M* 3-mercaptoproprionate according to the method of Laemmli (*26*). Gels were calibrated with fluorescein-tagged marker proteins visualized by fluorography (*27*). (The marker proteins were provided by Dr. Robert Duke, Hahnemann Medical College, Philadelphia, Pa.).

RESULTS

Characterization of MCA.—The MCA we used to detect Ia-like and HLA antigens (on the colorectal tumor cells) were characterized in two ways. First, their reactivity to a panel of T-lymphocytes, B-lymphocytes, and lymphomas was evaluated by immunofluorescence and complement-mediated cytotoxicity assays. Second, proteins precipitated by some of the antibodies were characterized in terms of molecular weight by SDS-PAGE (*see* below). Table 1 illustrates the specificity of 10 MCA tested against T-lymphocytes, non-T-cells (B-lymphocytes and monocytes), and three lymphoma cell lines—Raji, Daudi, and MOLT-4. Raji is a line of B-cell origin and expresses Ia-like and HLA, A-, B-, and C-antigens. Daudi is also B-cell derived and expresses Ia-like antigens, but not membrane-bound HLA (*28, 30*). MOLT-4, a T-cell leukemia, expresses HLA, but it does not express Ia antigens. Antibodies 7H.3, 8H.6, 8H.7, 8H.18, 41H.20, and 41H.30 react with B-lymphocytes and B-lymphoma

[f] Negative control, reacts with a single *N. meningiditis* serotype (*19*).

lines, but they do not react with T-cells. Consequently, they may recognize Ia-like antigens. Antibody 41H.16 reacts with all B-cells, but it does not react with Daudi which expresses Ia antigens; hence it may recognize a non-Ia B-cell marker. Its immunoprecipitation product is uncharacterized.

Antibodies 9H.1, 10H.7, and 41H.5 recognize T- and B-lymphocytes from all individuals and failed to react with surface HLA-negative Daudi cells, which suggests that these MCA might recognize HLA, A-, B-, and C-antigens.

Reactivity of MCA with the human colorectal carcinoma cell line LoVo.—Table 2 illustrates the reactivity of the MCA panel with LoVo with the use of three cellular binding assays: ELISA, indirect immunofluorescence, and RIA. The last two assays were done with trypsinized cells, and the ELISA was done with nontrypsinized, gluteraldehyde-fixed cells. Despite the differing types of treatments of the cells, the three assays showed excellent concordance, also demonstrating that the cellular ELISA assay can be used reliably for detection of cell surface antigens on adherent cell lines. The six MCA that reacted with the Ia-bearing B-cells but not T-cells reacted strongly with LoVo cells. In contrast, none of the three HLA-like MCA reacting with B-cells, T-cells, Raji, and MOLT-4 but not Daudi reacted with LoVo cells.

Immunoprecipitation of Ia-like, but not HLA-like, molecules from LoVo cells.—These results suggest that LoVo cells might bear surface Ia-like but not HLA-like determinants. Figure 1 demonstrates that three of our anti-B-cell MCA precipitate a bimolecular complex (heavy-chain mol wt = 34,000 and light-chain mol wt = 30,500) from LoVo cells. Consequently, they appear to recognize Ia-like antigens. The other three anti-B-cell MCA that react with LoVo (8H.7, 8H.18, 41H.20) were not good immunoprecipitating antibodies, although longer exposure time of the autoradiograms clearly showed two faint bands in the Ia region (data not shown). Figure 2 shows that three putative anti-HLA MCA (9H.1, 10H.7, and 41H.5) indeed precipitate a two-chain complex of molecular weights 44,000 and 12,500 from Raji cells. Consequently, they appear to recognize HLA, A-, B-, and C-antigens. However, the two anti-HLA MCA that were tested with LoVo (9H.1 and 41H.5) do not immunoprecipitate anything detectable from these cells.

Reactivity of the MCA panel with 16 human CCC lines.—We used the cellular ELISA assay for testing the MCA panel against human CCC lines. The MCA D228b, which reacts against a serotype-specific antigen of *N. meningiditis*, was used as a negative control, whereas 50H.19, which reacts with all human solid tumors we have tested, served as a positive control. In addition, we have tested myeloma proteins of all known isotypes and IgG subclasses and did not detect significant binding to CCC (data not shown). Marked heterogeneity in the expression of Ia-like and HLA markers detected by our MCA panel was noted (table 3). Two additional CCC lines were found to react with the same six anti-Ia-like MCA that reacted with LoVo. Unlike LoVo, these two CCC lines reacted strongly with all three anti-HLA MCA. Two of the CCC lines, SW-48 and SW-707, reacted only with the positive control MCA and did not react detectably with any of the anti-HLA or anti-Ia-like MCA. These are the only two lines classified in Leibovitz's group 1 (*19*). The two CCC lines from Leibovitz's group 2 (SW-480 and SW-620), which were derived from tumors at different sites from the same patient, reacted identically with all three anti-HLA MCA and none of the anti-Ia or other anti-B-cell MCA. Heterogeneity in the expression of different Ia-like and HLA determinants detected by our MCA among the CCC lines was also found. For example, WiDR expressed the determinants detected by anti-HLA MCA 9H.1 but not the HLA determinants detected by 10H.7 or 41H.5. SW-1116 and SW-1398, both Ia-like-negative, reacted with 9H.1 and 41H.5 but not with 10H.7. Two of the CCC lines, SW-948 and SW-1463, reacted with only one of the anti-Ia-like MCA, 7H.3, again suggesting heterogeneity in the expression of Ia-like determinants among the cell lines. None of the CCC lines reacted with MCA 41H.16, another B-cell marker possibly unrelated to Ia.

Binding of ^{35}S-labeled anti-Ia-like and anti-HLA MCA to selected CCC lines.—To confirm the results obtained by ELISA, we used another more quantitative assay, the cellular RIA, to

line CCRF-SB. Text-figure 1 demonstrates that 8H.6 binds to CCRF-SB LoVo, and SW-1417 but not significantly to SW-480 or SW-1222, and text-figure 2 shows that 9H.1 binds to all cell lines tested except LoVo, confirming the ELISA results.

HLA and Ia-like phenotype of LoVo subclones.—We established 12 limiting dilution subclones of LoVo to determine whether significant antigenic heterogeneity exists within the LoVo line. Like the parental line, all 12 subclones lacked all three HLA markers. Two out of 12 of the subclones failed to express Ia-like markers detected by MCA 8H.6, 8H.7, 8H.18, and 41H.30, but they continued to express strongly 7H.3 and 41H.20 (table 4). Immunofluorescence tests on subclones 4 and 6 confirmed the ELISA results and showed, as in the parental line (*see* table 2), that approximately 25–40% of the cells stained after treatment with 7H.3 or 41H.20.

DISCUSSION

It has become generally accepted that at least one explanation for tumor progression is the production in the tumor of variant clones of cells that vary in their malignant phenotypes (*31*, *33*). Those clones with a survival advantage will become dominant in a tumor but will, in turn, give rise to more variant clones. Conditions in vivo may result in the emergence of more aggressive and/or less antigenic variant sublines from the parent population. This hypothesis is supported by the data of several workers (*34–37*), who noted marked heterogeneity among tumor subclones. The results presented here demonstrate marked heterogeneity in the expression of Ia-like and HLA-like molecules on different human CCC lines as well as on subclones of one CCC line. One of our most interesting observations was the heterogeneity in the expression of different Ia-like and HLA determinants showing not only that some of our MCA detect different determinants but also suggesting that these determinants might be present on different molecules or that different conformations of the same molecules exist in various CCC lines. Our sequential immunoprecipitation data (unpublished observations) suggest that our anti-Ia-like MCA detect at least two and possibly three different Ia-like molecules on human lymphoblastoid cell lines. The data obtained from the LoVo subclones also suggest the existence of at least two Ia-like molecules on human CCC lines. The results of several recent studies in which MCA were used have suggested that the human Ia-like molecular pool is composed of several subsets of molecules (*38–44*). More work will be required to determine whether tissue polymorphism in the expression of different Ia-like molecules occurs and whether different Ia-like molecules have different functions or different effects on the immune system when present on tumor cell membranes.

Ia-like determinants have been unexpectedly detected most frequently on malignant melanoma cells (*8–12*) but also on several other types of nonlymphoid tumors (*10–15*). To the best of our knowledge this communication represents the first description of Ia-like antigens on human colorectal cancer cells, although others have reported negative findings based on testing only a few tumors (*10*). Five out of the 16 CCC lines reproducibly expressed at least one Ia-like marker. The reason for the variable expression of Ia-like antigens on certain solid tumors is not understood and could be due to abnormal expression of genes in cancer cells. Conversely, the presence of these molecules may be related to cell differentiation because Ia-like antigens may be restricted to particular stages of differentiation within certain cell lineages (*16*). Nevertheless, Ia-like antigens may serve as important tumor markers for immunodiagnostic purposes. The expression of these markers could relate to certain clinical parameters, such as extent of disease, ease and duration of remission induction, and perhaps survival. Indeed, it is known that Ia-like antigens control the specificity of several immunologic reactions and have been shown to affect the immunogenicity of certain tumor-specific antigens (*17*, *18*).

The immunofluorescence tests presented in table 2 showed that although most of the LoVo cells do not react with anti-Ia-like MCA, distinct subpopulation(s) of cells, comprising 25–50% of the total population, react strongly with MCA. We considered two mechanisms to explain the intratumor Ia-like antigen heterogeneity: 1) the existence of stable variants of Ia-positive cells in the cell line or 2) cell cycle regulation of Ia antigen expression. Two out of 12 of the subclones we generated lost reactivity to four of the anti-Ia-like MCA, but all retained at least one Ia-like molecule recognized by two of our MCA. We retested these subclones four times and found that the two variant subclones were highly stable. These data suggest that stable phenotypic variants exist within the LoVo tumor. Further biochemical studies will be required to determine whether or not the variant subclones synthesize the Ia-like molecules, which are undetectable at the cell surface. If we assume that similar Ia variants are found in fresh tumor tissue, it is possible that immunoselection of such variants could occur. It is of interest in this regard that Ia-like antigens on nonlymphoid human tumor cells can serve as efficient targets for antibody-dependent cellular cytotoxicity (*14*). The LoVo subclones were retested with use of the immunofluorescence test. Like the parental tumor, the percentage of Ia-positive cells remained in the 20–50% range, which suggested that cell cycle-related events are also responsible for the Ia antigen heterogeneity. This type of Ia antigen heterogeneity has recently been described for the cell cycle-related Ia expression on a murine B-lymphoma cell line (*45*).

Recent reports demonstrate the presence of Ia-like molecules on human endothelial cell surfaces, which can function in antigen presentation and lymphocyte triggering (*46, 47*). Inasmuch as lymphocytes must cross endothelial barriers to enter extravascular tissues during immune reactions and tumor cells must cross the same barriers to metastasize, Ia-like molecules might represent important recognition structures for organ-specific homing of both lymphocytes and tumor cells, especially in view of the recent reports suggesting the existence of multiple Ia-like molecules (*38–44*). The demonstration of tissue polymorphism in the expression of different Ia-like molecules might lend credence to this hypothesis.

Three indirect binding assays described in this paper failed to detect the HLA-like molecules detected by all three of our MCA on the surfaces of three of the human CCC lines. The apparent lack of detectable HLA was examined in detail with the LoVo CCC line. The immunoprecipitation experiments also failed to detect these molecules in the parental LoVo line. Twelve subclones of LoVo were found to remain HLA-negative, which suggested that if HLA-positive variant clones exist they must be present at relatively low frequency. Nevertheless, these cells may have contained HLA antigens but at a level undetectable by all the methods used. Using our MCA, we have found that the only other cell line that has the same phenotype is the Daudi Burkitt's lymphoma cell line. This cell line is known not to express cell surface HLA because it cannot synthesize β_2 microglobulin (*28–30*). Recently, Woda and co-workers (*48*) described 3 malignant lymphomas of the diffuse histiocytic type in which most of the tumor cells express monoclonal surface immunoglobulin and HLA-DR antigens but do not express HLA, A, B, C, or $\beta_2\mu$. Because it is possible that at least some of our anti-HLA MCA react against $\beta_2\mu$, we cannot rule out the possibility that heavy chain is also synthesized by these CCC lines.

LoVo was derived from a lymph node metastasis of a colorectal cancer patient. It maintains the characteristic morphologic and physiologic properties of a colorectal cancer, including the formation of acinar structures and the production of CEA [(*23, 24, 49*) and our unpublished results] and has been used as an important model for chemotherapy of colorectal cancer (*50*). The two CCC lines of Leibovitz's SW series, which were negative for all three HLA markers, were the only group 1 CCC lines included in our study. According to Leibovitz et al. (*19*), group 1 cell lines have a modal chromosome number of about 47 and synthesize small-to-moderate amounts of CEA. The WiDR cell line was found to lack two HLA markers, and the SW-1116 and SW-1398 lines lacked only one marker. This phenomenon might reflect tissue polymorphism in the expression of different HLA markers or molecules or indicate that HLA molecules exist in different configurations. The reduction of type I MHC molecules on tumor cells may have important biologic implications, e.g., for the associative recognition of tumor antigens by T-cells and hence for immunosurveillance (*18*). The apparent loss of HLA could have been due to immunoselection of HLA loss variants.

Further studies are in progress to determine whether clones of HLA-loss variants exist in fresh human tumors. It is of interest in this regard that a high proportion of non-transfused cancer patients may possess relatively high titers of cytotoxic anti-HLA and possibly anti-Ia antibodies in their sera (*51*).

Changes in Skin Cancer Morbidity Between 1971–72 and 1977–78[1]

Thomas R. Fears[2,3] *and* **Joseph Scotto**[2,4]

ABSTRACT—Skin cancer incidence rates for two geographic areas of the United States were analyzed for detection of significant changes in risk over a 6-year period (1971–72 to 1977–78). Changes in rates were examined by cell type, anatomic site, sex, and age. In general risk has increased, but the size of the increase varied by cell type, sex, and anatomic site. Statistically significant increases were limited to tumors of the basal type. The risk of basal cell skin cancer appears to have increased about 18% or almost 3% per year. Increases did not depend on age group. Among males the increases were most notable for sites other than face, head, and neck, whereas among females the increases were not associated with site.—JNCI 1982; 69:365–370.

In 1971–72 age-adjusted nonmelanoma skin cancer incidence rates ranged from 151 to 379 per 100,000 in four geographic areas of the Third National Cancer Survey (*1*). These incidence rates were far higher than the rate for any other single cancer site and substantially higher than any previously reported skin cancer incidence rates for the United States. In one location, Minneapolis–St. Paul, incidence apparently doubled in just 5 years (*2*). Unfortunately, the meaning of the increase was not clear. The average annual risk of developing the disease could have increased, but the change in incidence rates could have been due to varied or improved case ascertainment methodologies. To provide more data on skin cancer, the National Cancer Institute conducted a skin cancer survey during 1977–78 at several locations in the United States. Two of these locations, Minneapolis–St. Paul and San Francisco–Oakland, were also part of the 1971–72 study and were included in the new survey to provide the data needed to determine if the risk of developing skin cancer is changing. This report contains a summary of the data currently available from these two locations and an analysis of the observed changes in skin cancer incidence rates over the 6-year period by age, sex, anatomic site, and cell type.

MATERIALS AND METHODS

The data used in this report are from two special skin cancer surveys. The first study, covering a 6-month survey period, September 1971 through February 1972, was conducted as a part of the Third National Cancer Survey (*1*). Four locations participated. The second study was reported only recently (*3*) and covered a full 1-year period from June 1977 through May 1978. Eight locations participated. The two studies used the same protocol for the identification and recording of all nonrecurring nonmelanoma skin cancer (i.e., squamous cell or basal cell carcinomas). In addition to obtaining data from outpatient hospital files, special efforts were made to contact the offices of dermatologists, pathologists, radiotherapists, surgeons, and other physicians who see or treat skin cancer patients. Although clinically diagnosed cases were accepted, over 95% of the reported tumors were microscopically confirmed. Uniform reporting and monitoring procedures (both manual and by computer) were maintained at all study locations. The procedures and forms used are detailed elsewhere (*4*). We know of no substantive changes in registry methodology, methods of treatment, or medical care patterns in these locations, which would differentially affect the observed incidence. Two locations, Minneapolis–St. Paul and San Francisco–Oakland, are common to the two surveys. Only for these two locations can we obtain direct estimates of changes in incidence, which may have occurred between 1971–72 and 1977–78. Because the reporting of skin cancer is usually highest during the summer months, the difference in survey periods between the two studies must be considered. To adjust for any differences in reporting by month of diagnosis, we based the analysis on the incidence of newly diagnosed cases that occurred during the 6-month period common to both surveys, i.e., September through February. Because skin cancer is rare among nonwhites, analysis is limited to Caucasians only. The incidence rates given in this report are 6-month incidence rates among whites, which refer only to the September-through-February period in each survey.

The 1971–72 survey used population data from the 1970 census. For the 1977–78 survey, intercensal population estimates were required. Total population estimates for 1977 were provided by the Federal–State Cooperative Program for Population Estimates for each study location. Detailed estimates according to age, race, sex, and location were then obtained with data from the U.S. Bureau of Census to incorporate changes in birth, death, and migration patterns.

We assume throughout that for a particular age and sex stratum the distribution of the number of cases can be approximated by a Poisson distribution with a mean and variance equal to the expected number of cases. Such an approximation is quite good for large populations with a moderate average probability of developing the disease. We take the mean of these Poisson variables to be proportional to the population size and an exponential function of cell type, anatomic site, survey year, area, and age effects.

Let P_1 and P_2 represent the probability of developing skin cancer of a particular cell type at a given anatomic site during the first and second surveys, respectively. Then the

survey ratio, denoted by R, is simply P_1 divided by P_2, and $(R-1)\times 100\%$ is the relative change in the probability of developing the disease. Our analysis of the data from these surveys consisted of detailed testing and estimation of the relative change in incidences for a given sex, cell type, anatomic site, and age stratum. We assumed that the relative changes in incidence were the same for all age groups at both locations. We tested the appropriateness of the assumption by calculating the conditional maximum likelihood estimate of the common relative changes for each set of incidences and used that estimate to obtain goodness-of-fit chi-squares. We also considered the data for each individual geographic area. We took relative changes to be the same for all age groups but different for each location. In this case the assumption was further tested against the alternative that the relative change varied according to age by use of weighted regression on logarithms of relative changes. If the assumption appeared appropriate, using a normal deviate test we tested the hypothesis $H_0{:}R=1$ against the alternative $H_1{:}R\neq 1$.

The methods used here are based on the conditional distribution of test statistics in which the conditioning is on the sufficient statistics of nuisance parameters. These methods are quite accurate even when expected values are small. A detailed mathematical presentation of the methods is outside the scope of this report. The interested reader is, however, referred to Gart (*5*),[5] in which there is a careful mathematical derivation of the methods.

RESULTS

The Data

For San Francisco-Oakland and for Minneapolis–St. Paul, the number of patients and the 6-month incidence rates were tabulated for males and for females. Six age groups were used: 25–34, 35–44, 45–54, 55–64, 65–74, and 75–84. Rates and counts were tabulated for patients with basal cell carcinomas only and for patients with at least 1 squamous cell carcinoma. Since squamous cell carcinoma is not as common as basal cell carcinoma, the few cases with simultaneously diagnosed skin cancers of both cell types were included in the squamous cell counts only. The tabulations were made for 2 general groups of anatomic sites: The sites most frequently exposed to sunlight by both sexes FHN and the sites other than FHN that are less frequently exposed, such as upper extremities, trunk, and lower extremities. Cases with multiple cancer sites were included in the count for sites other than FHN if at least one of the sites was not FHN, whereas cases with multiple cancer sites of the FHN only were included in FHN only. Table 1 presents the tabulations for basal cell cancers, and table 2 provides a summary for squamous cell cancers. Table 3 summarizes the statistical analysis of the data. In text-figure 1 we plot the relative changes and their standard errors for each sex, cell type, area, and site group. A horizontal line at zero in these figures represents no change in the incidence rate.

Basal Cell Skin Cancer Among Males

After adjusting for geographic area, the assumption of constant relative increase over age groups fit the data for basal cell incidence rates among males. Basal cell skin cancer incidence rates among males have increased during 1971–72 to 1977–78. The increase is estimated to have been 18% over the 6 age strata. This increase was significant ($P<0.001$). The relative changes were not, however, consistent by site group. Basal incidence rates adjusted for age and area increased only 8% for FHN ($P=0.043$), quite different from a 69% increase found in sites other than FHN ($P<0.001$).

Changes in incidence rates for the individual FHN sites were inconsistent between geographic areas. For at least one geographic area, decreases occurred in the rates of scalp or forehead, eyelid, ear, and neck or supraclavicular tumors. Nevertheless, the rates for FHN sites when adjusted for area increased for each individual site except eyelid, but not one of these changes was significant. Changes in incidence rates for individual sites other than FHN indicated an increase at both geographic areas and all sites. There was a 91% adjusted increase in male basal incidence rates for upper extremities and a 54% increase in the incidence rates for lower extremities. Increases were notable for skin tumors on the trunk. However, the magnitude of the relative change at this site seemed to depend on age or geographic area. The incidence rates for San Francisco–Oakland increased 75–100% in the age groups 55–64, 65–74, and 75–84, whereas decreases were observed in younger age groups. The increases in San Francisco–Oakland are consistent with the increase observed in Minneapolis–St. Paul.

Basal Cell Skin Cancer Among Females

Basal cell skin cancer incidence rates among females increased during 1971–72 to 1977–78. For all sites combined there was an estimated increase of 18.5% ($P<0.001$). In contrast to the patterns observed among men, changes for women apparently do not depend on anatomic site. Area-adjusted incidence rates increased by 18% ($P<0.001$) for the more exposed FHN sites and by 23% ($P<0.026$) for sites other than FHN.

In regard to the individual sites of the FHN, increases were observed for tumors of the scalp or forehead, nose, cheek, chin, or jaw, neck, and lip. The increases in female

incidence rates were substantially larger than the increases for males at the same anatomic sites. By far the largest increase, 97%, occurred in the incidence rates for lip. This difference cannot be explained by changes in morphology coding (i.e., eighth to ninth revision of the International Classification of Diseases for Oncology) because anatomic site charts were utilized for identification of the exact tumor locations on the body. There were decreases in the rates for skin cancer of the ear in San Francisco-Oakland and of the eyelid in both locations. There were increases in the incidence rates for skin cancer of sites other than FHN, but they were less dramatic than those observed for males. Increases of 28, 53, and 40% were found for upper extremities, lower extremities, and multiple sites, respectively.

Squamous Cell Skin Cancer

Squamous cell skin cancer incidence rates are relatively small. They are based on few cases, and under the Poisson assumption they are quite variable. Small nonsignificant increases in rates for males were obtained. The rates for all sites combined increased 5%, the rates for FHN sites increased 4%, and the rates for sites other than FHN increased 10%. The increases in squamous cell skin cancer among rates for females are larger than those observed for males, 13% for FHN sites and 19% for sites other than FHN. The increases among females are consistent in size with those observed for basal cell skin cancer rates, but because of the higher variability of the rates for squamous cell tumors, these increases, like those for males, are not significant.

DISCUSSION

Recent changes in skin cancer incidence show that there have been increases in the incidence of the superficial, nonspreading tumors of the basal cell type. Changes in the incidence of squamous cell type are not definitive. There have been increases in general, but the changes seem to vary by sex and anatomic site. Certainly, more data are needed. The apparent difference between cell types is not easily explained. Perhaps the latent period for squamous cell carcinoma is different from that for basal cell carcinoma.

Among males increases in the basal cell incidence rates appear to be site-dependent with areas of the body not routinely exposed to sunlight showing the largest increases.

Text-figure 1.—Relative change in age-specific skin cancer incidence with standard error by cell type, sex, anatomic sites, and geographic area, 1971–72 to 1977–78. Let r_1 be the incidence rate of skin cancer in 1971–72 and r_2 be the incidence rate of skin cancer in 1977–78. Then $\mathrm{Var}(R)=\mathrm{Var}(r_2/r_1)$ is estimated by $[\mathrm{Var}(r_2)+R^2\mathrm{Var}(r_1)]/r_1^2$. A) Squamous cell carcinoma. B) Basal cell carcinoma.

TABLE 4.—*Annual relative change in skin cancer incidence rates by sex, cell type, and anatomic site*

Anatomic site	Relative change in incidence, %			
	Basal cell cancer		Squamous cell cancer

[b] $P<0.05$.

The small change in basal cell incidence rates among males for FHN therefore suggests to us that males increased the frequency or duration of their sunlight exposure only slightly. The large increase at the usually unexposed sites suggests, however, that the nature of exposure at these sites has changed. Perhaps men are wearing shorts and removing their shirts more often. Among females the incidence rates increased, but the increases were not so clearly associated with site. Rates for the frequently exposed sites of the FHN indicated large increases as did the incidence rates for less frequently exposed parts of the body. This general increase suggests that frequency and/or duration as well as manner of exposure may have changed among females. Perhaps women are spending more time outdoors today than in the past and wearing less protective clothing. The large increases observed for basal cell carcinoma of the lip among women may coincide with the practice in recent years of wearing less lipstick. Decreases in the rates for tumors of the eyelid are consistent with the practice of wearing sunglasses.

We found little or no evidence to support the hypothesis that relative changes in basal cell or squamous cell skin cancer depended on age for any site group, site, or sex. This finding is important since it implies that changes in nonmelanoma skin cancer incidence rates shift but do not distort the observed relationship between age and logarithmically transformed incidence rates (*6*).

The relative changes in incidence rates reported here are for a 6-year period between 1971–72 and 1977–78. These increases should not be compared with annual relative changes that are reported for other tumor types (e.g., melanoma). If we assume that the relative increase was the same in each year, then $(R^{1/6}-1)\times 100$ represents the annual relative increase that would have been observed. In table 4 we provide this estimate of the annual change in skin cancer incidence rates by sex, cell type, and site group.

There are problems that make the interpretation of the results of our study difficult: 1) We have used as our unit of study the populations of two SMSA's and concerned ourselves with population incidence rates. Care must be taken when making inference about the risks to individuals within these SMSA's, since the population hazard need not reflect changes in the individual hazard. 2) No measurements of the sizes of populations in these areas are currently available. Therefore, we must assume that our estimates of population size for 1977–78 do not contain any systematic errors over ages. If, in fact, such systematic errors are present, changes in incidence rates would be observed when there had been no change in the average probability of disease. 3) Finally, other factors of etiologic significance have not been included in this report. Since the probability of skin cancer is known to differ markedly among subpopulations, any change in the relative sizes of subpopulations could dramatically affect the average probability of the disease.

Isolation and Partial Characterization of Surface Components of Cell Line MDA-MB-231 Derived From a Human Metastatic Breast Carcinoma[1,2,3]

Evelyne Walker-Nasir,[4] **John F. Codington,**[4] **Marianne R. Jahnke,**[4,5]
Thomas C. Fuller,[6] *and* **Roger W. Jeanloz**[4,7,8]

ABSTRACT—Neuraminidase (*Vibrio cholerae*) treatment of human metastatic mammary carcinoma MDA-MB-231 cells grown in culture released 0.60–0.63 mg of *N*-acetylneuraminic acid from 10^9 cells. Incubation of intact cells with a modified trypsin and fractionation by gel filtration gave mainly *O*-glycopeptides. The presence of *O*-glycosyl-linked chains having one or two carbohydrate residues was confirmed by treatment of the glycopeptide fractions with galactose oxidase, followed by reduction with alkaline sodium borotritide and fractionation. The major glycopeptide fraction, which consisted of 53% carbohydrate and 47% protein, and a minor glycopeptide fraction each inhibited hemagglutination by peanut lectin. These results suggest the presence of *O*-β-D-galactopyranosyl-(1→3)-*O*-(2-acetamido-2-deoxy-α-D-galactopyranosyl)-(1→3)-L-serine (threonine) residues. The absorptive capacities for anti-HLA-A2 and anti-HLA-B8 antisera were slightly greater for intact than for lyophilized cells, which suggested that masking of these major histocompatibility antigens did not occur in intact cells.—JNCI 1982; 69:371-380.

Attempts by many laboratories during the past decade to correlate metastatic properties with the presence of macromolecular structures at the cell surface have not been conclusive. Some investigators, for example, have reported a correlation between metastatic potential and low concentrations of cell surface glycoproteins in mammary tumor cells (*1*), whereas others (*2-4*) have observed the presence of high concentrations of high-molecular-weight, endogenous *O*-glycoproteins in metastatic mammary carcinoma cells grown in vivo. However, metastatic potential may be achieved by more than one mechanism (*4*), and cell surface features involved directly in this process may vary with cell type, host, and environmental circumstances. The need for more intensive work in this area involving physicochemical and immunologic determinations on various metastatic tumor cell types is clearly indicated.

The availability of the well-characterized, metastatic cell line, derived from a human breast tumor, MDA-MB-231 (*5, 6*), which was reported to grow rapidly in culture (*6, 7*), offered the opportunity to study the chemical, immunochemical, and immunologic characteristics of the surface components of this cell and the possible role of these components in metastasis. Of particular interest was investigation of the possible presence of cell surface *O*-glycoproteins having high concentrations of carbohydrate chains. Investigators have reported the presence of large endogenous *O*-glycoproteins in high concentration at the surfaces of both mouse (*4, 8*) and rat (*9*) mammary carcinoma ascites cells with high metastatic potential. Furthermore, the presence of Thomsen-Friedenreich antigenic activity, presumably resulting from *O*-β-D-galactopyranosyl-(1→3)-*O*-2-acetamido-2-deoxy-α-D-galactopyranosyl residues linked to serine or threonine in the polypeptide backbone, has recently been observed in human mammary carcinoma tissue but not in normal breast tissue (*10, 11*). In our investigation of macromolecular structures at the surface of the MDA-MB-231 cell, particular attention was given to the possible presence of glycoproteins containing the Thomsen-Friedenreich antigen-like structure.

MATERIALS AND METHODS

Cells.—Cell line MDA-MB-231, established from the pleural effusion of a patient with metastasized mammary carcinoma (*5*), was obtained in the frozen state at the 75th passage from EG&G Mason Research Institute, Rockville, Md., at the suggestion of Dr. P. Gullino, National Cancer Institute, Bethesda, Md.

Cell culture and harvest.—Cells were grown in monolayer culture in Dulbecco's modified Eagle's minimum essential medium with L-glutamine (Grand Island Biological Co., Grand Island, N.Y.) and supplemented with 10% fetal bovine serum (M.A. Bioproducts, Walkersville, Md.), 100 U penicillin/ml, and 100 μg streptomycin/ml. Cells in 100-mm-diameter plastic tissue culture dishes (Falcon Plastics, Oxnard, Calif.) were incubated in humidified 5% CO_2–95%

ABBREVIATIONS USED: GLC=gas–liquid chromatography; MS=mass spectrometry; *m/z*=mass divided by charge; NHS=normal human serum; PAGE=polyacrylamide gel electrophoresis; SDS=sodium dodecyl sulfate; TPCK=chloromethyl L-(2-phenyl-1-*p*-toluenesulfonamido)ethyl ketone; T_R=retention time(s).

best copy available

air at 37°C. Cells free of mycoplasma[9] were used between their 11th and 20th passages. From monolayer culture, the cells were adapted to growth in suspension culture in spinner flasks at 37°C in the same medium as described above. Inocula of 5×10^5 cells/ml were used. After 4 days the cells ($\approx2\times10^6$ cells/ml) were harvested, washed, and counted with a hemacytometer, and their viability was determined by trypan blue exclusion (*12*). For this investigation, 1.2×10^9 cells (in six separate runs) were utilized.

Enzymes.—Neuraminidase (EC 3.2.1.18 from *Vibrio cholerae*, protease-free, 500 U/ml; Behring Diagnostics, Somerville, N.J.) was obtained in 1-ml vials. TPCK-treated trypsin (TPCK-trypsin, EC 3.4.21.4; Sigma Chemical Co., St. Louis, Mo.) was purified as described in (*13*). α-Amylase (EC 3.2.1.1, from porcine pancreas) was obtained from Sigma Chemical Co.; galactose oxidase (EC 1.1.3.9), glucose oxidase (EC 1.1.3.4, from *Aspergillus niger*), and peroxidase (from horse-radish) were obtained from Worthington Biochemical Corp., Freehold, N.J.

Physicochemical analyses.—The dry weight of cells was estimated as previously described (*13*). Cell surface sialic acid was determined by the thiobarbituric acid method (*14*) after incubation for 80 minutes with neuraminidase (150 U/ml in phosphate-buffered saline solution) at 37°C, with crystalline *N*-acetylneuraminic acid (Sigma Chemical Co.) as standard. The total amount of sialic acid in the washed cells was estimated as the sum of neuraminidase-liberated sialic acid plus the sialic acid detected (*14*) after treatment of the residual, neuraminidase-treated cells with 50 m*M* sulfuric acid for 1 hour at 80°C, neutralization of the cooled solution with barium carbonate, filtration, and passage of the solution through a column of Dowex 50W-X16 (H^+) ion-exchange resin (Bio-Rad Laboratories, Richmond, Calif.). The amount and composition of sialic acid were also determined by GLC (*15*). Protein was determined by the method of Lowry et al. (*16*) with bovine serum albumin (Sigma Chemical Co.) as standard. Hexoses were determined by the phenol-sulfuric acid procedure (*17*) with D-galactose as standard. Uronic acid was determined by GLC and by the procedure of Blumenkrantz and Asboe-Hansen (*18*) with D-glucuronic acid as standard and identified by GLC-MS (*see* below). Sulfate was estimated by the rhodizonate dye assay (*19*), after hydrolysis of the sample with 2 *M* HCl for 14 hours at 100°C, and by evaporation of the solvent under a stream of nitrogen.

GLC.—The carbohydrate composition of the lyophilized samples was determined after methanolysis, acetylation, *O*-deacetylation, and per-*O*-(trimethylsilyl)ation as previously described (*20*). The T_R are given relative to hexa-*O*-trimethylsilyl-*myo*-inositol. Amino acid analyses were performed by the method of Zumwalt et al. (*21*) on the same samples after hydrolysis with 6 *M* HCl for 24 hours at 110°C.

GLC-MS.—Fraction F100-III, eluted from a Biogel P-200 column (100–200 mesh; Bio-Rad Laboratories), was methanolized (≈35 hr at 85°C). The product was acetylated, *O*-deacetylated, reduced with sodium borodeuteride as previously described (*22*), and analyzed by GLC-MS with an instrument equipped with a computer. Methyl 2,3,4,6-tetra-*O*-trimethylsilyl-α-D-glucopyranoside and 1,6-anhydro-2,3,4-tri-*O*-trimethylsilyl-α-L-idopyranose were used as reference standards in MS. The intensities of the following diagnostic ions, compared with those of the corresponding deuterated fragments, observed after treatment of fraction F100-III, as just described, were *m/z* 231, 133, 117, 103, and 89 and 305, 133, 129, 117, 103, and 89, respectively.

Column chromatography.—Fractionations were performed at 4°C on columns of Biogel P-4 (200–400 mesh), Biogel P-100 (100–200 mesh), and Sepharose 6B (Pharmacia Fine Chemicals, Piscataway, N.J.) with 50 m*M* pyridine acetate (pH 5.3) as eluent. The void volume of the gel-filtration columns was determined with blue dextran 2000 (Pharmacia Fine Chemicals).

Gel electrophoresis.—PAGE (10%) with SDS (0.1%) was performed according to the method of Laemmli (*23*) in Tris-HCl buffer (pH 8.0) with bovine serum albumin and α_1-acid glycoprotein as standards. The bands were stained with 0.1% Coomassie brilliant blue in 45% methanol and 7.5% acetic acid.

Proteolysis of viable cells.—Batches of $2\text{–}5\times10^8$ viable cells were incubated at 4°C in Dulbecco's phosphate-buffered saline (pH 7.0) with a modified trypsin (18 μg/ml), as previously described (*24*). The supernatants were lyophilized, and bound sialic acid [after treatment with neuraminidase (*25*)], protein (*16*), and total hexose (*17*) were determined.

Purification and fractionation of cell surface components.—A solution of lyophilized trypsinates in pyridine acetate (50 m*M*, pH 5.3) was applied to a column (2.2×84 cm) of Biogel P-4. Fractions (6.0 ml) were eluted with the same buffer and monitored for protein (*16*) and total hexose (*17*). The major carbohydrate- and protein-containing fractions from the first peak (F4-I, 6.5 mg) (text-fig. 1) were combined and passed through a column (2.7×91 cm) of Biogel P-100 (text-fig. 2). Fractions (6.0 ml) were examined for protein (*16*) and total hexose (*17*). Material eluted just after the void volume (F100-II, 1.0 mg) was fractionated on a column (0.8×45 cm) of Sepharose 6B. Fractions (0.5 ml) were analyzed for protein content by absorbance at 278 nm and, on this basis, were divided into five fractions

Adsorption of Vicia graminea *lectin by intact cells.*—As previously described (*26, 27*), the amount of lectin adsorbed was calculated from the amount remaining in solution (following incubation with intact cells), a value determined by the capacity of the unadsorbed lectin to agglutinate human erythrocytes of N-blood group specificity.

Adsorption-inhibition assays.—The inhibitory activity of glycopeptide fractions for the agglutination of neuraminidase-treated, human type O erythrocytes by *Arachis hypogaea* (peanut) lectin (Sigma Chemical Co.) was determined according to a modified procedure of Osawa et al. (*28*). After incubation of 25 μl of the lectin (amount previously found to agglutinate 50% of the erythrocytes) and 25 μl of each glycopeptide fraction at appropriate twofold dilutions for 3 minutes, 50 μl of sialic acid-free erythrocytes (7×10^8 cells/ml) was added. The concentration of lectin that completely inhibited the agglutination of the erythrocytes within 60 minutes was recorded.

---

[9] Mycoplasma contamination was tested by the Bacteriology Department, Massachusetts General Hospital, on batches of cells grown in antibiotic-free medium.

Alloantiserum adsorptions.—Expression of the HLA histocompatibility alloantigens at the surface of the tumor cells was determined by the adsorption-inhibition lymphocytotoxic assay. The following alloantisera were used: MGH No. 29 with HLA-A2 antibody specificity, CW-2, anti-HLA-B8, GLO-2, anti-HLA-A1, and NHS. Antiserum (50 µl at the optimal dilution) was incubated with viable or lyophilized cells at three concentrations (1×10^5, 1×10^6, and 1×10^7 cells). Comparison was made of suspension- and monolayer-grown viable and lyophilized cells, respectively. After 60 minutes with intermittent mixing at room temperature, the adsorbed antiserum was separated from the cells by centrifugation (5 min, 15,000×*g*) and kept frozen at −30°C until back-titration was performed. Both adsorbed and unadsorbed sera were assayed for residual cytotoxic antibody with the National Institutes of Health cytotoxicity technique (*29*) and the more sensitive Amos modification of this method, which incorporates a wash step following the incubation of target cells with the antiserum (*30*). All sera were tested undiluted and diluted 1:2 with fresh rabbit serum (Pel-Freez Biologicals, Inc., Rogers, Ark.) as a source of complement. Two unrelated individuals, who possessed the antigens reported (*31*) to be expressed on the cell line (HLA-A2 and HLA-B8), donated target lymphocytes for back-titration of the antisera as described above. In addition, for specificity control, a nonadsorbable HLA antiserum (GLO-2, anti-HLA-A1) and NHS were also incorporated; the unrelated individuals also expressed HLA-A1 for this purpose.

Labeling of terminal D*-galactose and 2-acetamido-2-deoxy-*D*-galactose residues with tritium: Cleavage of carbohydrate chains and fractionation in a gel-filtration column.*—Incubation of 100–200 µg of each sample with 5 U of galactose oxidase (150 U/mg) in phosphate-buffered saline solution (pH 7.0) was performed for 30 minutes at 37°C. Approximately 500 µCi of sodium borotritide (246 Ci/mol) was added. After 1–2 hours at 22°C, 700 µg of sodium borohydride (Ventron Corp., Alfa Products Division, Danvers, Mass.) was added, and the solution was kept for an additional 45 minutes. The mixture was acidified with acetic acid and kept for 2 hours before the addition of sodium hydroxide to a 0.1-*M* concentration and of sodium borohydride to a 1.0-*M* concentration. The mixture was incubated for 72 hours at 37°C and then acidified with acetic acid. After evaporation to dryness in vacuo, the residue was dissolved in anhydrous methanol, and the solution was evaporated to dryness. The residue was dried by several additions and evaporations of methanol in vacuo.

Each residue dissolved in 0.1 *M* pyridine acetate (pH 5.3) was applied to and eluted at 4°C from a column (1.5×127 cm) of Biogel P-2 (200–400 mesh) with 0.1 *M* pyridine acetate (pH 5.3). The radioactivity of aliquots of fractions (2.5 ml) was counted in a Packard scintillation counter. The column had been previously calibrated with a sample of 2-acetamido-2-deoxy-D-galactitol, prepared by reduction of 2-acetamido-2-deoxy-D-galactose (Pfanstiehl Laboratories, Inc., Waukegan, Ill.) with excess sodium borohydride at neutral pH, with a sample of the reduced disaccharide 2-acetamido-2-deoxy-3-*O*-β-D-galactopyranosyl-D-galactitol obtained from epiglycanin, as previously described (*32*), and with a sample of α_1-acid glycoprotein.

RESULTS

Release of Glycoprotein Material From the Cell Surface

The amounts of sialic acid, neutral carbohydrate, and protein material removed by the action of enzymes from viable MDA-MB-231 cells grown under monolayer and suspension culture conditions were similar for both growth conditions, although the trypsinates of suspension-grown cells appeared to contain slightly more glycoprotein material (table 1). The cells possess a large surface area, and the diameter of the cells grown under each set of conditions was found to be similar (≈15 µm). The amount of cell surface sialic acid liberated by neuraminidase represents about 70–75% of the total sialic acid of the cells (*24*), because approximately 25–30% more sialic acid was detected after mild acid hydrolysis of the viable, neuraminidase-treated cells. No free sialic acid was detected before neuraminidase treatment, and the only sialic acid detected at the surface of MDA-MB-231 cells was *N*-acetylneuraminic acid; no *O*-acylated derivatives were observed, because identical sialic acid values were obtained for untreated samples and for samples briefly pretreated with sodium hydroxide and neutralized with hydrochloric acid prior to incubation with neuraminidase (*15*). No neutral carbohydrate was detected in material released from the cell surfaces in the control incubations without added proteolytic enzyme; some protein, however, was liberated (5–9% of the amount released by trypsin).

Fractionation of Cell Surface Fragments Removed by Proteolysis

[g] Determined by the method of Lowry et al. (*16*).

grown MDA-MB-231 cells gave, at the void volume, a major peak (F4-I; text-fig. 1) (≈6–7 mg/10^9 cells), which represents about 21–25% of the total surface glycoprotein material (28.5 mg) recovered from the Biogel P-4 column. (For carbohydrate and amino acid composition, *see* table 2.) Other fractions eluted later from the Biogel P-4 column represented minor components of glycopeptide nature and were not further studied. Fractionation of F4-I on a column of Biogel P-100 gave three major peaks (F100-I, F100-II, and F100-III; text-fig. 2) at fractions 25, 47, and 66, respectively. (For carbohydrate and amino acid compositions, *see* table 3.) All three F100-fractions contained uronic acid and sulfate.

proportion of glucose, i.e., over 60% of the total carbohydrate. Fractions F6B-I, F6B-III, and F6B-V contained sulfate and uronic acid (table 4), the proportion of uronic acid being the highest and that of sulfate being the lowest in fraction F6B-V. The presence of glycogen in F100-I and F6B-I was suggested by the characteristic mahogany color observed under the microscope after addition of Lugol's iodine reagent; it was further indicated by treatment of both fractions with α-amylase, followed by the determination of the D-glucose liberated with glucose oxidase, according to the method of Dahlqvist (*33*). Control samples of both fractions were treated under identical conditions but without the addition of α-amylase; no free D-glucose was detected in the samples.

D-Glucose was identified in all material obtained from the cell surface, although the relative amounts of this sugar differed widely in the various samples. D-Glucose is not a constitutent of most glycoproteins, although it has been found as an integral part of a few glycoproteins (*34–36*) and of glycopeptides isolated from the membranes of rat liver mitochondria (*37*). However, in the high-molecular-weight fractions from both the Biogel P-100 and Sepharose 6B columns, the large quantities of glucose observed seem to arise from a glucose polymer, possibly glycogen, which might have accumulated on the cell membrane as a result of the growth conditions of the cells and the high glucose content of the medium used (*38*). However, a high-molecular-weight glucose polymer that appears to be a metabolically stable form of glycogen or limit-dextrin has recently been found in rat brain glycopeptide preparations (*39*). Removal of the glucose polymer before fractionation was not possible.

The proportions of uronic acid in the various column fractions (tables 2–4) correspond to the sum of the values obtained by the colorimetric method (*18*) (found to be more sensitive for free uronic acid than the determination by GLC) and the values obtained by GLC of uronic acid derivatives, possibly in the forms of an iduronolactone (T_R 0.83; Walker-Nasir E, Reinhold VN, Jeanloz RW: Unpublished results) and uronic acid-containing oligosaccharides. These oligosaccharides, which did not react in the colorimetric procedure (*18*), were present in small amounts in many column fractions because of the unusual resistance of the D-glucuronic acid glycosidic linkages to acid-catalyzed hydrolysis. By subjection of the materials to two cycles of methanolysis (*see* "Materials and Methods"), the release of free uronic acid was increased, but arabinose (T_R 0.56) arising from decarboxylation of glucuronic acid was also formed in a large amount; a peak at T_R 1.27 (unidentified 2-amino-2-deoxyhexose) was also observed. Under the methanolysis conditions used in the present study, only a trace amount of arabinose was observed on the chromatograms of all the fractions described, except for F6B-II. In fraction F6B-V, a uronic acid disaccharide represented the major component; peaks corresponding to uronic acid-containing oligosaccharides were also observed on the chromatogram. These components might have arisen from hyaluronic acid, which appears to represent the preponderant glycosaminoglycan in this fraction (*see* table 4) and which is rather resistant to methanolysis (*40*).

The uronic acids present in fraction F6B-I, as well as in F100-III, were identified as described in "Materials and Methods." A net increase in the size of the glucose peak on GLC (T_R 0.90), observed after reduction with sodium borodeuteride, and deuterium incorporation into that particular hexose (m/z 233, 135, 119, 105, and 91) established the presence of glucuronic acid as the major uronic acid in the original, surface-associated glycosaminoglycans. Deuterium was also incorporated into another hexose, which was observed as a minor peak in the chromatogram after reduction; this sugar was tentatively identified (GLC–MS) as idose (T_R 0.95; m/z 233, 135, 119, 105, and 91), indicating the presence of iduronic acid (arising from the iduronolactone derivative, T_R 0.83) as the second uronic acid at the surface of the MDA-MB-231 cell. Additional evidence for the presence of iduronic acid was obtained by the identification (GLC–MS) of a small proportion of 1,6-anhydro-[^{2}H]idose (T_R 0.80; m/z 307, 135, 131, 119, 105, and 91). No other deuterated carbohydrate component was found. Peaks possibly corresponding to arabinose, xylose, gluco-4,5-enepyranosyluronic acid, an unidentified hexosamine, and reduced *N*-acetylneuraminic acid derivatives were also observed on the chromatogram.

Fraction F6B-II consisted of glycopeptides only and showed the highest values for total carbohydrates and amino acids, as well as the highest proportions of both serine and threonine; the values for aspartic acid and glutamic acid were also high. The yield of this purified glycopeptide fraction from the crude, high-molecular-weight glycopeptide fraction (F100-II) was about 10–15%, and it accounted for about 0.75% of the total cell surface glycoprotein material released by mild proteolysis. Fraction F6B-V contained neutral sugars, *N*-acetylglucosamine, and uronic acid; no sialic acid, *N*-acetylgalactosamine, or proline was detected, and only a minor amount of threonine was observed (GLC). On SDS–PAGE, fraction F6B-V did not enter the gel and gave a single, narrow band at the origin, which was stained with Coomassie blue. The molecular weight of this fraction may be estimated superior to 100,000.

V. graminea Lectin Adsorption Experiments

In experiments performed with intact, suspension-grown, washed tumor cells from two passage numbers, no adsorption was observed, suggesting that these cells do not have exposed *V. graminea* receptors on their surface.

Determination of Inhibitory Activity Against Hemagglutination by *A. hypogaea* (Peanut) Lectin

Fraction F6B-II completely inhibited the agglutination of neuraminidase-treated erythrocytes with peanut lectin at a concentration of 2.5 μg/ml, whereas fraction F6B-III completely inhibited the agglutination at 20 μg/ml. Fractions F6B-I and F6B-V showed no inhibitory activity. These data suggest that both fractions F6B-II and F6B-III contain receptors for peanut lectin, fraction F6B-II possessing a much stronger inhibitory activity than fraction F6B-III.

Antiserum Adsorptions

In these experiments (*see* table 5), no reactivity was observed with NHS (negative control) antiserum, indicating that the adsorption procedure used released no lymphocytotoxins. Experiments with GLO-2 alloantiserum (having HLA-A1 specificity) clearly showed that the adsorption procedure did not remove antibody in a nonspecific way. (HLA-A1 is not expressed on the cell surface of the adsorbing cell line.)

All the cells tested, suspension- and monolayer-grown, viable as well as lyophilized, consistently adsorbed a large amount of HLA-A2 antiserum, even at the lowest concentration of cells, i.e., 10^5 cells. The data also indicate that slightly more HLA-A2 antigen is present on the viable than on the lyophilized cells. The results of the experiment performed with the HLA-B8 antiserum are less clear, but nevertheless they seem to indicate that HLA-B8 is weakly expressed on the cells tested, possibly in a slightly higher concentration or site density on the viable than on the lyophilized cells.

Identification of *O*-Glycosyl-Linked Carbohydrate Chains

Carbohydrate chains containing tritium-labeled terminal galactose and 2-acetamido-2-deoxygalactose residues were tentatively identified by comparison of their effluent volumes with those of labeled authentic monosaccharides and disaccharides. No detectable amounts of chains longer than two residues appeared to be released from fraction F6B-II or F6B-V, as shown in text-figure 3. Fraction F6B-III gave peaks that corresponded to those of both authentic samples, 2-acetamido-2-deoxy-3-*O*-*β*-D-galactopyranosyl-D-galactitol and 2-acetamido-2-deoxy-D-galactitol. Two additional peaks appeared, however, in the region where the reduced disaccharide was expected. The identity of the two (possibly three) reduced oligosaccharides has not been established. No additional peak appeared after treatment of fraction F6B-III with *V. cholerae* neuraminidase (*15*) prior to labeling and cleavage from the macromolecule. Indeed, a shoulder present in the elution profile of the untreated material disappeared after treatment with the enzyme. Fraction F6B-III as well as fractions F6B-II and F6B-V exhibited a prominent peak that corresponded to that of 2-acetamido-2-deoxy-D-galactitol. Fraction F6B-V appeared to possess a small amount of labeled disaccharide material, but this peak

TEXT-FIGURE 3.—Fractionation on a column of Biogel P-2 of tritium-labeled, reduced oligosaccharides cleaved from glycopeptides by alkaline borohydride reduction. Eluent: 0.1 *M* pyridine acetate (pH 5.3). Tritium (cpm) in products derived from F6B-II (-----), F6B-III (• • • •), and F6B-V (——) was plotted against the effluent volume. Authentic standards were a) 2-acetamido-2-deoxy-3-*O*-*β*-D-galactopyranosyl-D-galactitol, b) 2-acetamido-2-deoxy-D-galactitol, and c) α_1-acid glycoprotein.

was missing in the elution profile of fraction F6B-II, which indicated the release of a chain of only one residue.

DISCUSSION

In an attempt to relate the metastatic properties of the human mammary ductal carcinoma MDA-MB-231 cell line to the concentration and type of carbohydrate-containing macromolecules at the cell surface, we discovered several types of structures previously found to be associated with cancer in general and metastasis in particular on the surfaces of these cells. The presence of an unusually high concentration of sialic acid (1.2×10^9 residues/cell) would result in a large net negative charge on these cells (*41*). It has been suggested that the charge from sialic acid at the cell surface may be responsible for allotransplantability in mouse ascites cells (*42*). Furthermore, sialic acid has been shown to prevent tumor rejection by masking antigen sites on the cell surface (*43*).

These investigations confirmed the findings of other workers (*44*) that high concentrations of glycosaminoglycans are present at the surfaces of these cells grown in culture. Indeed, uronic acids and sulfate groups, resulting from the cleavage of cell-associated glycosaminoglycuronans by mild proteolysis, were identified in the major column fractions (with the exception of fraction F6B-II), in addition to glycopeptide components (tables 3, 4). The presence of heparan sulfate at the surface of the MDA-MB-231 cell has been described (*44*). The high content of sulfate and the high molar ratio (almost 2:1) of sulfate to uronic acid in fraction F100-I (*see* table 3) are possibly due to a disulfated disaccharide structure in this material. The possible presence of sulfated glycoprotein fragments in fractions F100-I and F100-III must also be considered. In any case, the unusually high sulfate content in some of these fractions probably reflects a complex array of sulfated glycoproteins and glycosaminoglycans at the MDA-MB-231 cell surface. Although the role(s) of such substances as heparan sulfate at the cell surface of tumor cells is not understood (*45*), shielding of cell surface receptors has been suggested (*46*). A role for hyaluronic acid in masking cell surface antigens in a variety of mouse fibrosarcoma and carcinoma cells has recently been suggested (*47*).

The presence of glycoproteins containing *O*-glycosyl-linked carbohydrate chains at the surfaces of MDA-MB-231 cells was first suggested by the carbohydrate and amino acid compositions of isolated glycopeptide fractions (table 4). The proportion of *N*-acetylgalactosamine in fractions F6B-II and F6B-III is higher than that reported for other types of cell surface glycopeptides (*48, 49*). The presence of *N*-acetylgalactosamine as well as galactose in fractions F6B-I, F6B-II, and F6B-III indicates the occurrence of *O*-glycosyl-linked chains at the surfaces of these cells. The proportion of serine and threonine is likewise high, especially in fraction F6B-II, which was obtained from the crude, high-molecular-weight material in 10–15% yield, and thus appears to represent the major glycopeptide fraction of these cells. In this fraction these two residues represent 31% of the amino acids, and the carbohydrate content represents 53% of the weight of the material. In addition to sialic acid, *N*-acetylgalactosamine, and galactose, this fraction contained *N*-acetylglucosamine, mannose, and glucose; the proportion of aspartic acid was also high. These data suggest the presence of both *N*- and *O*-glycosyl-linked oligosaccharides in the glycoprotein molecules. The hemagglutination inhibition studies indicate that in fraction F6B-II *O*-glycopeptides are preponderant or that they are exposed (*50*). Fractions F6B-I, F6B-III, and F6B-V probably contain mixtures of both *N*- and *O*-linked carbohydrate chains as well as glycosaminoglycans. These components have been found at the surface of Ehrlich ascites carcinoma (*41, 51*), hepatoma ascites (*49, 50, 52*), and melanoma cells (*53*). The major glycoprotein fraction from the plasma membranes of AH-66 rat hepatoma cells was reported (*52*) to contain both *O*- and *N*-glycopeptides having related chemical composition, in analogy with our findings.

Consistent with the presence of short *O*-glycosyl-linked chains was the capacity of both fractions F6B-II and F6B-III to inhibit the agglutination of neuraminidase-treated human erythrocytes by peanut lectin. It has been suggested that the receptor for this lectin in macromolecules is the serine- or threonine-linked disaccharide *β*-D-Gal*p*-(1→3)-D-GalNAc (*54*). This structure is similar to that proposed for the Thomsen-Friedenreich antigen, which is reported to be the carbohydrate precursor of both M- and N-blood group substances (*55*). It has been reported (*56, 57*) that this structure is associated with human malignant, but not benign, mammary tumors, and its detection by a tuberculin-like skin test has been used as a diagnostic test for human breast cancer (*58*). However, recent observations (*59, 60*) point to a more complex interpretation, and possibly the antigenic specificity of the disaccharide is strongly affected by the amino acid sequence adjacent to the site of chain attachment.

The presence of *O*-glycosyl chains in isolated glycopeptide fractions (table 4) was confirmed by the use of labeling techniques (text-fig. 3). The terminal galactose residues of the intact glycopeptides were labeled with tritium by galactose-oxidase treatment, followed by reduction of the 6-aldehyde group with sodium borotritide (*61*). Cleavage of the *O*-glycosyl chains under reductive conditions was followed by gel-filtration fractionation (text-fig. 3). Only fraction F6B-III, which demonstrated weak hemagglutination-inhibitory activity, showed a major peak corresponding to that of a standard sample of the reduced disaccharide. A second peak, corresponding to that of authentic *N*-acetylgalactosaminitol, was also obtained from this fraction. Surprisingly, fraction F6B-II, which had the highest inhibitory activity in the peanut-lectin experiment, gave only this peak. Fraction F6B-V, which demonstrated no inhibitory activity, showed a major monosaccharide and a minor disaccharide peak. These seemingly contradictory results may be explained either by failure of the alkaline borohydride reduction to release the disaccharide or by failure of investigators to recognize that the *N*-acetylhexosamine itself may serve as a receptor for the lectin in macromolecules (*62*).

It is somewhat surprising that *O*-glycoproteins should represent important cell surface components of the MDA-MB-231 cell line after a prolonged period in culture (95 passages), since it has been shown (*42*) that the environment in which a cell line grows is essential for the biosynthesis of some surface components. Thus the large, endogenous glycoprotein epiglycanin of the TA3-Ha mammary carcinoma cell of the strain A mouse is hardly detectable after several weeks in suspension culture (*63*), whereas it represents the major surface component when the cell is grown in the ascites form. A similar observation has been made in the case of the 13762 rat mammary adenocarcinoma (*64*). Attempts have been made to grow the MDA-MB-231 cells in the ascites form in the nude (*nu/nu*) mouse (Walker-Nasir E, Codington JF, Jeanloz RW: Manuscript in preparation) to observe the formation of the surface glycoproteins under these conditions; it was found, however, that this cell line, like most human carcinoma cell lines reported (*65*), does not grow as an ascites tumor. In spite of the in vitro suspension culture conditions used in the present study, glycopeptides with *O*-glycosyl carbohydrate chains were isolated from the surfaces of these cells; it seems possible that these glycopeptides represent major surface components in the original carcinoma from human metastatic cells.

The HLA antigens of the MDA-MB-231 cell line were reported (*31*) as HLA-A2, HLA-B8, and HLA-W14. Previous observations, made in this laboratory, had demonstrated that the adsorptive capacity of the non-strain-specific, murine TA3-Ha cells for anti-$H\text{-}2^a$ antibody was increased manyfold by disruption of the cell surface by lyophilization. This effect is probably due to unmasking of $H\text{-}2^a$ antigens at the cell surface (*66*). It was of interest, therefore, to test this hypothesis in human tumor cells by the use of antisera specific for the reported HLA-A and HLA-B determinants of the aforementioned line. The observation that the adsorptive capacity in intact and lyophilized cells did not differ significantly suggests that neither HLA-A2 nor HLA-B8 antigens are masked at the surfaces of the intact cells. The data further suggest the possibility, from the quasi total removal of antibody with as few as 10^5 cells, that the MDA-MB-231 cell is homozygous for HLA-A2 antigens.

The presence of *O*-glycoproteins has been associated with both allotransplantability (*67*) and metastatic potential (*64*) in experimental tumors grown in vivo. The possibility exists that the metastatic properties of the human tumor cells might have been lost in culture, and the results described here would then not necessarily relate to those obtained with the original cancer cells. According to data from several investigators (*1*, *68*) suggesting that the property of metastasis is intrinsic and that the inherent properties of tumor cells determine the metastatic character of the tumor cells in the host, it is possible that the in vitro cultured MDA-MB-231 cells have retained their metastatic character and would exhibit this property in vivo. In support of this hypothesis is the observation that the in vitro cultured cells had retained the characteristics (morphology, growth pattern, karyotype, and histocompatibility antigens) of the original tumor cells isolated from the pleural effusion (*5*).

An ideal situation would, of course, involve a comparison of primary and metastatic tumors of the same cell types. The difficulties inherent in such a study with human material are, however, obvious. Large quantities of cells from an established and stable line, derived from the original metastatic cells, would be required, and no reliable method for the determination of the metastatic character of the established line is available.

Although it seems possible that the presence of *O*-glycoproteins is associated with the metastatic character of the MDA-MB-231 tumor cells, several other factors, including those discussed in this report (i.e., high sialic acid and glycosaminoglycan concentrations), may play a role in this phenomenon. The complex process of metastasis may be accompanied by other events that might vary with each type of cell or tumor and with the environmental circumstances of the cell itself.

α_1-Proteinase Inhibitor Production by Human Adenocarcinomas Xenotransplanted Into Nude Mice[1,2,3]

Dorothy Lee,[4,5] **Dan Shochat,**[6] *and* **David V. Gold**[6]

ABSTRACT—Human colon adenocarcinomas xenotransplanted into BALB/c nude mice were examined for the ectopic synthesis of α_1-proteinase inhibitor(s) (α_1Pi). Tumor extracts were prepared by homogenization followed by molecular sieve chromatography on Sepharose 4B. Fractions with immunoreactive α_1Pi were concentrated and adsorbed onto a concanavalin A-Sepharose 4B affinity column, then eluted, concentrated, and analyzed. All 4 colon tumors examined produced α_1Pi with full antigenic identity to normal human plasma α_1Pi. Electrophoretic mobilities of 3 of the tumor-derived α_1Pi were different from the electrophoretic mobility of the normal human plasma α_1Pi. Activities of the inhibitors were determined by the reaction of each tumor extract with pancreatic elastase (PE) followed by immunoelectrophoresis of the reaction mixture against both anti-human α_1Pi and anti-PE antisera. Two of the tumor-derived α_1Pi examined were active in inhibiting PE. —JNCI 1982; 69:381–385.

The suggestion has been made that tumor cell proteinases may facilitate invasion of host tissues by the malignant tumor (*1*). In support of this suggestion are the many observations of increased levels of proteinases capable of digesting connective tissue matrix components within the tumor environment. High concentrations of plasminogen activators were shown to be produced by a number of different transformed cell lines (*2–4*). Increased cathepsin-B activity in malignant tumors as compared to the activity in benign tumors has been correlated with increased metastatic potential (*5, 6*). Liotta et al. (*7*) described the production of a specific basement membrane type IV collagenase by a metastatic tumor.

As a consequence of these studies, interest has arisen in regard to the distribution of Pi in tumors. Maintenance of a balance between proteinases and Pi within the tumor cell microenvironment may be critical in tumor growth regulation. The major serum Pi (α_1Pi) has been found associated with tumors. Yoshimura et al. (*8*) reported the synthesis of α_1Pi by yolk sac, hepatoblastoma, renal cell, and colon carcinomas xenotransplanted into nude mice. Later, Akatsuka et al. (*9*) confirmed these findings by immuno-electron microscopic localization of the α_1Pi in the endoplasmic reticulum and Golgi apparatus. In the present study we have isolated α_1Pi produced by human colon carcinomas xenotransplanted into nude mice and examined their antiproteinase activities and immunochemical properties.

MATERIALS AND METHODS

Tumors.—Human colon carcinomas xenotransplanted into nude mice were supplied by Dr. D. Dexter (Roger Williams General Hospital, Providence, R.I.). The tumors were transferred in nude BALB/c mice for at least 15, but not more than 30 generations. Tumors were transferred when they approximated 1×1×1.5 cm in size. The tumors were carefully excised, cleaned of obvious connective tissues, and minced into 1- to 2-mm cubes. A 25% suspension was prepared with Hanks' balanced salt solution, and 0.5 ml of this suspension was injected sc into the backs of the mice. Generation time for each of the tumors was about 3–4 weeks. DLD-1 was a poorly to moderately differentiated adenocarcinoma. Clone A and clone D were derived from DLD-1 by the soft agar method. Clone A was aneuploid, whereas clone D was diploid. DLD-2 was a moderately differentiated adenocarcinoma. The in vitro characteristics of the cell lines were described in (*10*).

Partial purification of α_1Pi from the tumors.—The tumors (2 g) were washed with cold deionized water, minced into 1- to 2-mm cubes, and then homogenized with 0.1 *M* NH_4HCO_3 containing 0.5 *M* NaCl (5 ml/g wet weight of tissue) in a homogenizing chamber (Omnimixer; Ivan Sorvall Inc., Norwalk, Conn.) at high speed for 2 minutes while on ice. The homogenate was centrifuged at 48,000×*g* for 30 minutes, the supernatant was collected, and 10-ml aliquots were chromatographed on a Sepharose 4B column (2.5×100 cm), equilibrated, and eluted with the same buffer. The column was previously calibrated with normal human serum to determine the elution volume of α_1Pi. The fractions within the α_1Pi region were pooled and concentrated by ultrafiltration (PM10 membranes; Amicon Corp., Lexington, Mass.) to about twice the size of the starting volume. This material was dialyzed against 1 liter of deionized water and then two changes of 2 liters of 0.1 *M* sodium acetate buffer (pH 6.0) containing 0.15 *M* NaCl and 0.001 *M* each of $CaCl_2$, $MgCl_2$, and $MnCl_2$. The dialyzed material was applied to a Sepharose-Con A (Pharmacia, Piscataway, N.J.) column 2.5×10 cm, equilibrated, and eluted with the same buffer. The attached fraction was desorbed with 0.2 *M* α-methylglucoside prepared in the buffer. The partially purified α_1Pi was dialyzed against several changes of 0.5 *M* NH_4HCO_3 and

lyophilized. The lyophilized preparation was redissolved with a minimum amount of buffer (100–200 μl) and was used for further study.

Analytic procedures.—Immunodiffusion, immunoelectrophoresis, and rocket immunoelectrophoresis were performed according to the methods of Ouchterlony (*11*), Grabar and Williams (*12*), and Laurell (*13*), respectively. Normal human serum was employed as a standard. Purified mouse α_1Pi was from Dr. S. K. Chan (University of Kentucky, Lexington). Rabbit anti-α_1Pi was obtained from Dako through Accurate Chemical and Scientific Corp., Hicksville, N.Y. The activity of the isolated α_1Pi preparations was demonstrated by their ability to inhibit PE. To 50 μl of the α_1Pi preparation we added 2 μl of a stock solution of porcine PE, 5 μg/μl in 0.07 *M* barbital buffer (pH 8.6; Elastin Products, St. Louis, Mo.), at room temperature for 20 minutes with constant stirring. Samples (10 μl) of the reaction mixture were subjected to immunoelectrophoresis with the simultaneous use of rabbit anti-α_1Pi (Dako) and rabbit anti-porcine PE (provided by Dr. H. Carp and Dr. A. Janoff, State University of New York at Stony Brook). Immunoelectrophoresis was conducted in 0.016 *M* sodium barbital and 0.014 *M* sodium acetate buffer (pH 8.8), with 3 V/cm of agarose gel for 90 minutes at room temperature.

RESULTS

Extracts (1 g tissue/5 ml buffer) of xenotransplanted human colon carcinomas were examined by immunodiffusion for the presence of α_1Pi. A weak precipitin line was noted for the DLD-2 extract, whereas no precipitin lines were observed for the other tumors. The possibility existed that the concentration of α_1Pi in these other tumors was below the detection limit of the method employed. When we attempted to examine a more concentrated sample however, we found that these tumor extracts could not simply be concentrated due to the presence of relatively large quantities of mucin, which formed highly viscous solutions upon concentration. To avoid this difficulty, we performed a semipurification of the α_1Pi by molecular sieve chromatography on a calibrated column to obtain an α_1Pi-containing fraction and a subsequent lectin affinity chromatography on a Con A–Sepharose 4B column. All the α_1Pi antigen-reactive material, as determined by immunodiffusion, was adsorbed to the Con A–lectin column. The desorbed material, after lyophilization and reconstitution, served as our sample for further analyses. The yields of semipurified α_1Pi (quantitated by rocket immunoelectrophoresis with the use of normal human serum as a standard) were 34.5, 70.5, and 49.5 μg/g tissue for DLD-1, DLD-2, and clone D, respectively. The material obtained from clone A was insufficient for this analysis.

Immunodiffusion performed with rabbit anti-human α_1Pi antiserum demonstrated that human plasma and xenotransplanted human colon carcinomas contained immunologically identical α_1Pi (fig. 1). Moreover, when absorbed with tumor-derived α_1Pi preparations, the antiserum lost all its reactivity against the plasma α_1Pi. A mouse plasma fraction that had been prepared in an identical manner did not react with the antiserum in immunodiffusion. In addition, purified mouse α_1Pi (0.5–5 mg/ml) did not react with the antiserum in immunodiffusion. By immunoelectrophoresis we confirmed that the DLD-1-derived α_1Pi had an electrophoretic mobility identical to that of the human plasma α_1Pi, whereas the mobilities of the α_1Pi isolated from DLD-2, clone A, and clone D were slower than the mobility of the plasma inhibitor (fig. 2).

We examined the biologic activities of three of the isolated tumor-derived α_1Pi preparations by testing the abilities of these preparations to form complexes with porcine PE. The α_1Pi concentrations in the preparations used in the experiment were determined by rocket immunoelectrophoresis and were found to be 9.4, 4.6, 6.6, and 17.4 μg/μl for DLD-1, DLD-2, clone D, and the diluted human plasma, respectively. When free, active α_1Pi was allowed to react with porcine PE, an enzyme inhibitor complex was formed that was reactive with both anti-α_1Pi antiserum and anti-PE antiserum. This complex had an electrophoretic mobility intermediate between that of the cathodal PE and anodal α_1Pi (fig. 3). The α_1Pi isolated from DLD-1 and DLD-2 were biologically active, whereas the α_1Pi from clone D was inactive.

DISCUSSION

Several lines of evidence suggest that proteases may play an important role in the tumor–host relationship. Consequently, maintenance of a proper balance between proteases and Pi may be essential in the regulation of tumor growth. Indeed, many synthetic and natural antiproteinases have the ability to retard tumor growth. Active site-alkylating agents such as the chloromethyl ketones *N*-tosyl-L-lysyl chloromethyl ketone and *N*-tosyl-L-phenylalanyl chloromethyl ketone reduced the growth of several transformed mouse and hamster cell lines (*14–16*). These inhibitors as well as the competitive inhibitor tosyl-L-arginyl methyl ester inhibited tumorigenesis in mouse skin (*17, 18*). Leupeptin, antipain, chymostatin, elastatinal, pepstatin, and bestatin have been found in many cases to inhibit the early stages of transformation (*18–21*). Natural antiproteinases such as soybean trypsin inhibitor, beef pancreas trypsin inhibitor, ovomucoid, and Trasylol (aprotinin) have been shown to inhibit the growth of a variety of transformed cell lines (*14, 15, 22*).

Colon epithelium in its normal state is not considered to be a plasma protein-producing organ. Our results, however, show that some colon carcinomas produce a protein which is antigenically identical with plasma α_1Pi of the tumor donor's species (and in some cases is an active Pi). The tumor xenografts that we studied did not secrete sufficient protein to enable its detection in the sera of their hosts, but the inhibitor could be demonstrated in extracts of the tumors.

The observed slower electrophoretic mobility of three of the tumor-derived α_1Pi may indicate the existence of either structural differences between the plasma and the tumor α_1Pi or different Pi phenotypes. Since more than 90% of the general population produce α_1Pi of the Pi MM phenotype (*23*), it would be a rare coincidence to have such a large population of variant Pi phenotypes in such a small sample. It would appear that the first explanation for the variant electrophoretic mobilities of the tumor-derived α_1Pi is more tenable.

Activity of α_1Pi was clearly established in 2 of these tumors, DLD-1 and DLD-2. The inactivity of α_1Pi from clone D may have resulted from prior interaction with proteinases liberated by clone D tumor cells, although the normal electrophoretic mobility of the clone D inhibitor would not be consistent with degraded or complexed α_1Pi. Alternatively, α_1Pi from clone D may have been more susceptible to denaturation during processing. Since human α_1Pi can be inactivated by cell-generated oxygen-free radicals (*24*, *25*), clone D cells may be metabolically more active in this regard than DLD-1 or DLD-2 tumor cells. Of course, clone D tumor cells may simply synthesize an inactive form of α_1Pi.

The physiologic significance of antiproteinase production by tumor cells is unknown. Local concentrations of active Pi may be important in modulating tumor proteinases and in this manner affect neoplastic spread. Conversely, because these same antiproteinases also inhibit enzymes released from host leukocytes (some of which participate in immune cytolysis of tumor cells), the production of these antiproteinases may compromise a vital, host defense mechanism. Clearly, further exploration of the regulatory effect of tumor cell products on tumor growth is warranted.

Increasing Trends of Multiple Myeloma Mortality in England and Wales; 1950–79: Are the Changes Real?[1,2,3]

Ramon **Velez**, *M.D.*, *M.Sc.*,[4,5,6] **Valerie Beral**, *M.R.C.P.*,[7] *and* **Jack Cuzick**, *Ph.D.*[8,9]

ABSTRACT—National statistics for England and Wales for the period of 1950–79 were examined to study the secular trends in multiple myeloma mortality and to evaluate the extent to which these changes may be due to biases associated with improvements in medical care. Age-adjusted mortality has increased more than fivefold during this 30-year period. Contrary to the impression obtained from clinical series, a slightly greater increase in age-adjusted mortality has occurred in males. Examination of age- and sex-specific mortality trends showed that the greatest apparent increase in myeloma mortality occurred in individuals over 70 years of age. The data are consistent with either a cohort effect, indicating a true increase in mortality, or an age-dependent diagnostic effect in which a greater percentage of deaths among the elderly are now being certified as myeloma. Analyses of mortality data by social class and region point toward improved case ascertainment being responsible for at least part of the apparent increase in reported mortality. The increase in reported mortality in the younger age groups may reflect a true increase in the incidence of this disease. This increase, however, would account for only a proportion of the total increase, even when extrapolated to the older age groups.—JNCI 1982; 69:387–392.

The apparent increase in incidence and mortality from multiple myeloma has become the subject of increasing interest. In the United States the reported increase in incidence of myeloma has been proportionally greater than that for any other site of cancer (*1–3*). However, a recent study of the population of Olmsted County, Minnesota, which has been under careful medical surveillance by the Mayo Clinic for several decades, has failed to show any increase in the incidence of the disease (*4*). The purpose of this study was to determine whether a similar trend in myeloma mortality has occurred in England and Wales and to assess the extent to which these changes may be due to change in diagnostic factors. Our analyses are based largely on routinely collected, published, and unpublished vital statistics for England and Wales. Comparisons have also been made with data from a cancer registry in Texas, where secular trends are tabulated for 3 ethnic groups (*5*).

MATERIALS AND METHODS

Mortality data were obtained from the Registrar General's Statistical Review for England and Wales (*6*) for the period of 1950–73 and from the OPCS Mortality Statistics (*7*) for the period of 1974–79. Unpublished mortality data by region for England and Wales were also obtained from OPCS.

Multiple myeloma has been separately classified under the ICD rubric 203 since the sixth revision of the ICD in 1948. There have been no changes in this classification in subsequent revisions.

The denominators for rate calculations for England and Wales are based on census year populations and intercensal estimates published by the Registrar General and OPCS. Age- and sex-adjusted myeloma mortality rates for England and Wales were calculated by the direct method with the use of the World Health Organization's European population standard. The data on standardized mortality ratios by social class were obtained from the Registrar General's decennial supplements (*8–10*). The regression lines of logarithm of incidence versus calendar year fitted to the Texas Cancer Registry data have been determined by the least-squares method. The analyses of age, cohort, and calendar year effects by a log–linear model was done by the same method as that used by Holman et al. (*11*).

RESULTS

Review of vital statistics.—In 1979 there were 1,602 deaths attributed to multiple myeloma (ICD 203) in England and Wales (*7*). This statistic represents approximately 1% of all cancer deaths and 18% of deaths from cancers of the lymphatic and hematopoietic system. Although these numbers by themselves are not particularly striking, the proportional increase in mortality from myeloma since 1950 is noteworthy. Since the case fatality rate for multiple myeloma is high, changes in mortality should reflect changes in incidence rates over time.

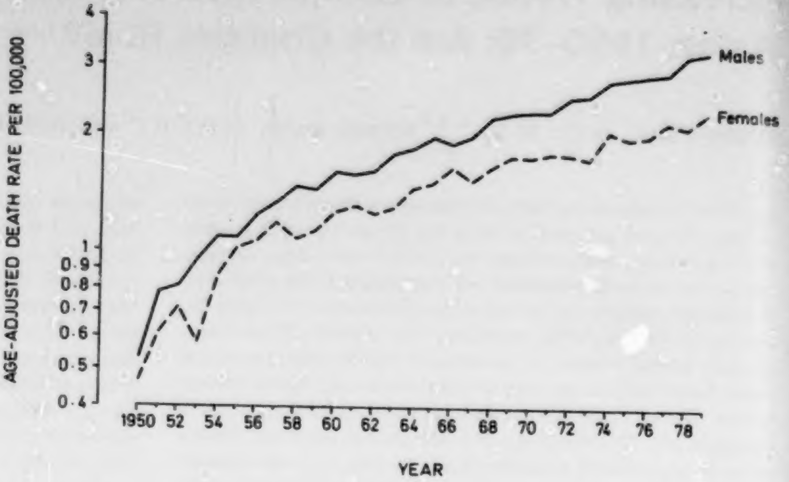
TEXT-FIGURE 1.—Death rates for multiple myeloma in England and Wales, 1950–79. Age-adjusted to the European standard population.



The age-adjusted mortality trends for both sexes from 1950 to 1979 are shown in text-figure 1. The proportionate increase during this 30-year period was 515% for males and 398% for females.

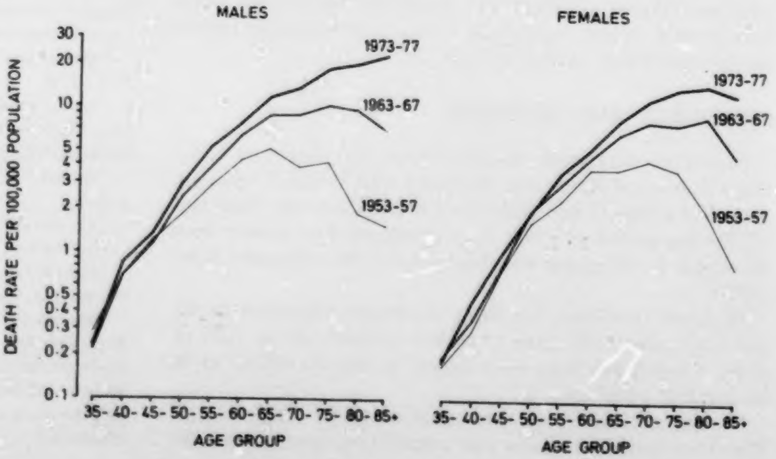
The sex ratio of age-adjusted mortality rates shows an excess of males which, remarkably, has increased in recent times. In 1950 the male:female ratio was 1.15, whereas it was 1.26 in 1960, 1.31 in 1970, and 1.42 in 1979.

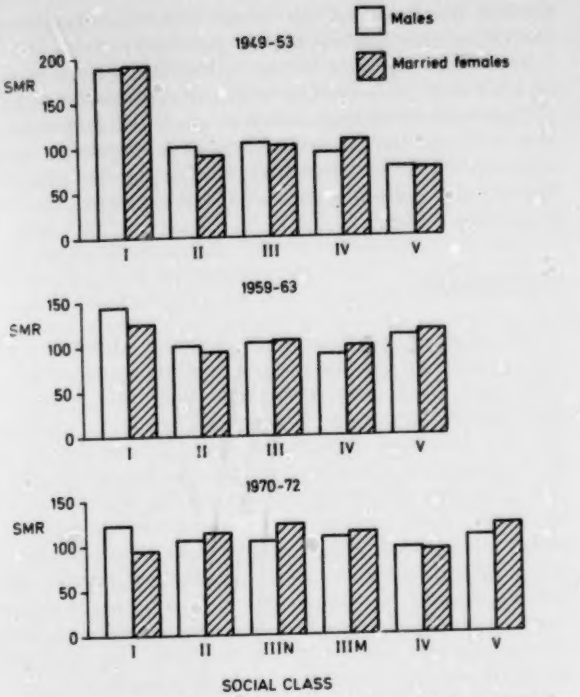
Text-figure 2 illustrates the changes in age- and sex-specific multiple myeloma mortality rates for the 5-year periods 1953–57, 1963–67, and 1973–77. Although some increase has occurred in all age groups, most of the increase in myeloma mortality has been concentrated in the older age groups. Consequently, the shape of the age–mortality curve has changed over time: In 1953–57 peak mortality was at ages 65–69 in males and 70–74 in females, but in 1973–77 the mortality rates continued to increase with advancing age for both sexes.

Social class.—Text-figure 3 summarizes SMR by social class for occupied males and females for the periods of 1949–53, 1959–63, and 1970–72. During 1949–53 a high SMR was found among social class I males and females, while other groups were similar and no clear trend was seen across social classes II through V. The same pattern was apparent during 1959–63, but the excess SMR was smaller in social class I. By the last 5-year period excess SMR had almost disappeared, and the rates among different social classes became similar.

It is useful to compare these observations with the change for leukemia which occurred at an earlier time. Table 1 compares mortalities for all types of leukemias and for all cancers for occupied males by social class for the periods of 1930–32, 1949–53, 1959–63, and 1970–72. The general pattern for leukemias is similar to that for myeloma, although a clear trend is not seen for high SMR among the higher social classes (I and II) and low SMR in the lower social classes (IV and V). These differences were most marked for the period 1930–32 and again have diminished over time. In contrast, the pattern for mortality from all cancer by social class shows a gradient in the opposite direction, with excess mortality among classes IV and V and lesser mortality among the other social classes. For all cancers, the trend with social class has become more marked in recent times—a reflection, for the most part, of the greater reduction in

TEXT-FIGURE 2.—Age and sex-specific death rates for multiple myeloma over 5-yr periods during the last 3 decades in England and Wales.





TEXT-FIGURE 3.—Standardized mortality ratios for multiple myeloma by social class in England and Wales.

smoking which has led to less lung cancer among social classes I and II.

Geographic variations.—Text-figure 4 shows the SMR for multiple myeloma for the standard regions of England and Wales (1976–78). There was some variation in SMR by region with the highest mortality in the Southwest (SMR=113) and Southeast (SMR=105) and the lowest mortality in the Northwest (SMR=88) and East Midlands (SMR=91).

Cohort analysis.—Text-figure 5 portrays mortality by birth cohort. This is plotted on a log–log scale so that a power law age-incidence curve appears as a straight line. This simple type of age-incidence curve is suggested by general principles (*12*) and provides a good fit for cancer at a number of sites (*13*). The fit to the present data is also quite good. The shifting of the curves to the left with more recent cohorts is what one would expect if successive cohorts were experiencing a greater mortality from this disease. The increases are largest between the earlier cohorts but continue until the 1905 birth cohort when the curves appear to have almost stabilized. A more mathematical analysis (*11*) can be based on a model that includes terms to account for both cohort effects and calendar year effects (that could arise from an age-independent change in diagnostic or certification practices). Such a model attributes the bulk of the increase to a cohort effect. A model that corrects for age and birth cohort fits the data extremely well (χ^2 for error =42.07 on 30 df), and no further improvement is obtained if calender year terms are included (χ^2 for error =38.65 on 27 df). A model that includes only age and calendar year terms does not fit so well (χ^2 for error =561.8 on 40 df), and a much better fit is obtained when the cohort terms are included (χ^2 for error =38.65 on 27 df). However, the calendar year variables do not accommodate an age-dependent improvement in diagnosis and certification (which could masquerade as a cohort effect), and this likely possibility must be considered in the assessment of the validity of this model. This model assumes that the logarithm of the expected mortality rates in each 5-year calendar period and 5-year age group is a linear combination of indicator func-

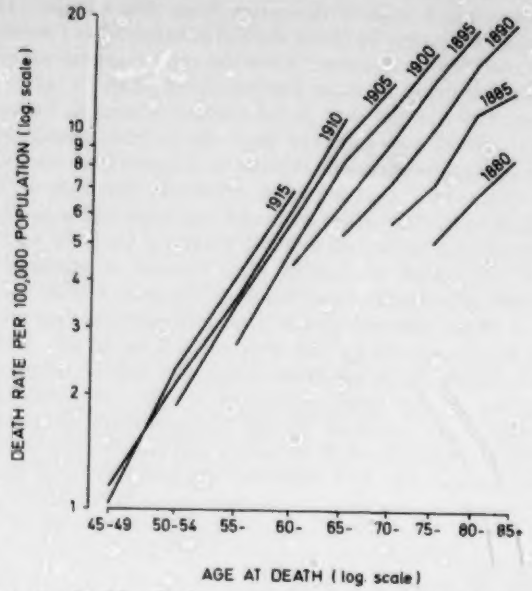
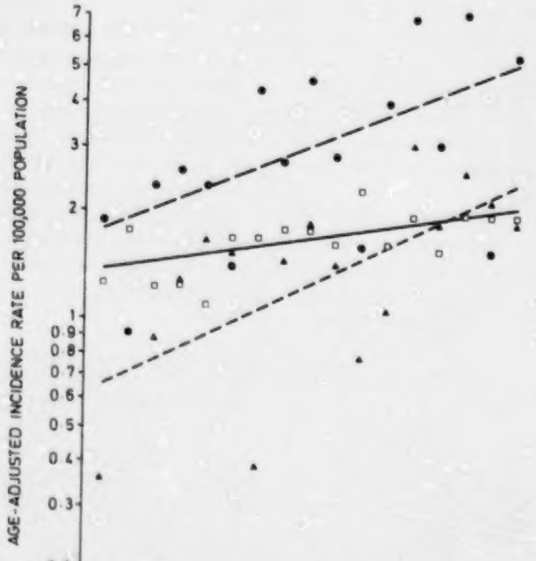
tions for 5-year age groups, 5-year birth cohorts, and 5-year calendar periods, and that the variations from the expected rates are independent Poisson random variables. A more detailed discussion of this model based on data from a number of countries will appear elsewhere.



TEXT-FIGURE 5.—Mortality from multiple myeloma in England and Wales in different cohorts born in 5-yr periods between 1880 and 1915.



TEXT-FIGURE 6.—Age-adjusted multiple myeloma incidence rates by ethnic group in Texas, 1950–1966. 1960 U.S. population used as standard. □——□, whites; ●——●, non-whites; ▲----▲, Spanish surnamed.

Texas cancer registry.—Shown in text-figure 6 are the age-adjusted multiple myeloma incidence rates for white, Spanish, and nonwhite populations living in a defined geographic area in Texas. The slopes of the rise of the regression lines of logarithm of incidence versus calendar year are steeper for Spanish and nonwhite populations compared to the white population.

DISCUSSION

The clinical presentation of multiple myeloma varies widely, with initial symptoms ranging from vague migratory bone pain, back pain, pathologic fractures, pneumonia, neurologic symptoms, and/or anemia to acute renal failure (*14, 15*). Diagnosis requires the aid of various tests, which have changed in their type and availability in the last 50 years. The first diagnostic test was the examination of urine for Bence Jones protein (*16*). Unfortunately, this test is positive in less than 50% of proven cases of this disease (*17, 18*). Thus other ancillary tests, such as bone marrow examination, skeletal X-rays, serum, and urine electrophoresis must be employed when this diagnosis is suspected. Before these procedures became widely available, the diagnosis of myeloma was often confirmed only at autopsy (*19*).

The gradual introduction of these diagnostic tests has spanned nearly 4 decades. Although bone marow examinations were first performed in 1929 (*20*), it was not until 1938 that the value of this procedure was recognized in the diagnosis of myeloma (*21*). It remained an infrequently used procedure, however, until the late 1940's, when a greater understanding of the cell types in normal marrow made the identification of abnormalities easier (*22*). Needle biopsies, that could be taken easily under local anesthetic, as opposed to the more difficult and painful trephine cuts used previously, became available in the 1950's and early 1960's and also led to the wider use of bone marrow investigation (*23, 24*). Similarly, serum electrophoresis was first described as being of diagnostic value in myeloma in 1938 (*25*). However, the method was laborious and remained a research tool until the 1950's (*26–28*), when, with the development of paper and cellulose acetate electrophoresis, this procedure became more widely available. We inquired at 10 London teaching hospitals to establish the time when serum electrophoresis became available. The responses gave the average year when this occurred as 1956, with a range from 1950 to 1962.

A diagnosis of multiple myeloma is highly dependent on the use of medical facilities and laboratory tests. The effects of these factors must be taken into consideration when one interprets mortality statistics (*29*). The sharpest increase in reported mortality rates occurred between 1950 and 1960 (text-fig. 1). This increase coincides with the period of the most rapid advances in the laboratory diagnosis of this disease.

The age-adjusted male-to-female mortality ratio reveals a slight excess of males in the 1950's that has increased in the next 2 decades. This finding is in striking contrast to the impression gained from clinical series in which a larger male preponderance was seen in the early part of this century (*19*) and is less apparent now. In 1961 Martin (*30*) reported the male-to-female ratio of cases of myeloma seen in London teaching hospitals as 3:2. More recently, Waldenstrom (*31*) has pointed out that in his recent experience the sex ratio has shifted toward a preponderance of females. The early large male excess is possibly partly an artifact due to a bias that used to exist (particularly before the introduction of the National Health Service) in favor of hospital referral of males rather than females for the investigation of obscure diseases (*32*), and its disappearance may be partly due to changes in referral patterns and in the sex distribution of the aged population. A greater percentage of females are now alive in the age groups in which myeloma incidence is highest, and the early case series were based on numbers and not rates. For example, in 1979 64% of the population of England and Wales above age 70 were female, whereas in 1950 only 59% were female. This bias can be removed by studying age-adjusted rates instead of cases for the two sexes (text-fig. 1), where the size of the normal population is accounted for.

Kyle et al. (*33*) examined the death certification of 31 patients in whom myeloma had been diagnosed at the Mayo Clinic in Olmsted County, Minnesota, during the period of 1945–64. He found that myeloma had been recorded as the underlying cause of death in 23 cases (74%). By contrast, in studying the recorded cause of deaths in a sample of incident cases from the Third National Cancer Survey, 1970–71, Percy et al. (*34*) found that 96% of the 699 incident cases of myeloma were certified as dying of this disease. This suggests that an increased awareness by clinicians of multiple myeloma, associated with changes in diagnostic habit and death certification, may contribute to the apparent increase in mortality trends.

MacMahon (*35*) has previously commented on the greater reported mortality from myeloma in social class I in the period 1949–53. A trend in the same direction has also been seen for the leukemias. The proportionate increase in mortality from leukemias earlier this century has been exceeded only by greater increases in lung cancer and coronary heart disease mortality (*36*). Although radiation exposure has been implicated as a causative factor in both leukemia (*37*) and myeloma (*38*), the increase in leukemia has been attributed primarily, although not exclusively (*37*), to improvements in diagnosis and better access to medical care (*36*), which may well be true also for myeloma.

Further support for the hypothesis that underascertainment is related to social class and access to medical care is provided by an examination of the data from a cancer registry in Texas (*5*), where cancer incidence in white, Spanish, and non-white populations has been analyzed. Both the Spanish and the non-white group represent socioeconomically disadvantaged populations. Over time both of these groups have benefited from greater access to medical care, and the increase in incidence of myeloma has been more pronounced in these 2 ethnic groups (text-fig. 6).

Studies of leukemia incidence have indicated that there is a consistent selective underascertainment among the elderly (*39–41*). Meadors (*40*) has suggested that this is the result of attributing leukemia deaths in the elderly to diseases of old age and infections. If correct diagnosis is a factor in myeloma mortality rates, as laboratory investigations increase, the greatest increases in registered mortality would be among the elderly where underdiagnosis is most prevalent. It is apparent from text-figure 2 that while myeloma mortality rates have increased in all age groups, the change is far greater in the older age groups.

Regional mortality data for England and Wales also support the view that access to medical care may be important in the diagnosis of myeloma. Mortality from all causes and all cancers is highest in regions in the North and lowest in the Southeast (*42*), but the reverse is true for myeloma (text-fig. 4). This observation is consonant with the disproportionately greater availability of medical facilities in the South (*43*).

In conclusion, it appears that technical improvements in the diagnosis of myeloma, as well as greater access to medical care especially among the elderly, have contributed to the increased recognition, and hence to the reported mortality, from this disease. Similar arguments were put forward to explain the reported increase in lung cancer earlier this century (*44, 45*), yet the increase in lung cancer was real. In the case of lung cancer, the increases were first noted in males, suggesting a specific etiologic agent much of which was later identified as cigarette smoking (*46*). For myeloma, the increase occurred in both sexes and has been only slightly greater in males, suggesting that any major new putative factor must have been introduced across broad sections of the population. The extremely good fit of the data to a model with only cohort effects also suggested that the increase may be at least partly real. Although much of the apparent increase in incidence of myeloma may be due to changes in diagnostic practice and referral, myeloma is certainly not as rare as it once was thought to be. Our knowledge of the etiology of this disease is meager and requires further investigation.

Changes in Clonal Expression During the Course of Acute Leukemia: Possible Subsets in Childhood Leukemia[1,2]

ABSTRACT—We studied cell surface markers and chromosomes in the leukemia cells of a boy with the initial diagnosis of acute lymphocytic leukemia during 18 months from diagnosis to demise. During this time he received induction therapy, underwent bone marrow transplantation, and relapsed. The leukemia cells expressed three membrane phenotypes during different stages of disease: T-cell at diagnosis; T-cell, B-cell, and monocyte during the induction period; T-cell in the first relapse after bone marrow transplantation; and T-cell and B-cell during the terminal stage. Some cells expressed markers of two cell types, indicating a common origin of these cells. Cytogenetic studies during post-transplantation relapse showed abnormal marker chromosomes that indicated two major sublines. However, there was enough sharing of other aberrant chromosomes to suggest that these two populations presented sublines within the same neoplastic clone. We suggest that these leukemia cells were derived from a pluripotential cell prior to differentiation into cells of the lymphoid and monocytic series. This particular case may represent a subset of acute leukemia and may account for the resistance to conventional therapy.—JNCI 1982; 69:393–399.

The ALL of childhood is considered to have its origin in the lineage of lymphoid cells. Alternatively, in CML cytogenetic and enzyme evidence (*1–7*) indicates origin from a pluripotent marrow stem cell.

Recently, a case of biclonal lymphoblastic and myeloblastic leukemia (*8*) was described, although the possibility that these two cell lines might have originated from a single clone was not completely excluded.

We have made a similar observation in a child who was considered to have ALL at diagnosis. During the course of leukemia, however, the malignant cells underwent a series of changes demonstrated by morphology, histochemistry, immunological surface markers, and cytogenetic studies. Moreover, evidence suggested that the cells were derived from a single malignant clone. The response of the patient to antileukemia chemotherapy was extremely poor, and the disease recurred after bone marrow transplantation.

CASE SUMMARY

A 6-year-old white boy was hospitalized in March 1978 because of pallor, lethargy, and swelling of the eyes, hands, and abdomen. Spleen and liver were palpable 12 and 3 cm below their respective costal margins. The WBC count was 319,000/mm^3 with 92% blasts. A bone marrow aspirate revealed 96% undifferentiated lymphoblastoid cells. They were most similar to lymphoblastic leukemia L_2 by French-American-British criteria (*9*). Both PAS and Sudan black stains were negative. Chest X-ray was normal. The diagnosis of ALL was made. The patient was treated with vincristine, prednisone, and L-asparaginase with only a temporary reduction in the number of peripheral blast cells. When the WBC count rose to 141,000/mm^3 with 88% blasts on the 16th day of therapy (April 78), a repeat bone marrow aspirate revealed 76% primitive cells, which appeared more like monoblasts than lymphoblasts. These cells reacted minimally with PAS stain and not with Sudan black. They stained positively for nonspecific esterase and did not react with naphthol AS-D chloroacetate esterase stain. The diagnosis was therefore changed to acute undifferentiated leukemia. Chemotherapy was continued with the addition of daunomycin and *β*-cytosine arabinoside, and a bone marrow remission was obtained.

Because of concern about the patient's long-term prognosis and because he had a younger brother with identical HLA-A, HLA-B, and HLA-D, the decision was made to undertake bone marrow transplantation while he was in complete remission. After informed consent was obtained (*10*), the patient was prepared with 2 doses of 60 mg

Walsh for her excellent typing of the manuscript.

cyclophosphamide/kg body weight/day, followed by a single 800-rad dose of total-body irradiation. The bone marrow transplant was performed on January 15, 1979, when the patient received 6.5×10^8 nucleated marrow cells/kg body weight. Thereafter, he received methotrexate at regular intervals for prevention of graft versus host disease (*11*). Extensive red cell typing had been done on both donor and recipient before transplantation. A repeat red cell antigen profile done in March 1979 revealed the patient to have c-antigen of the Rh group, the one informative antigen that distinguished the donor from the recipient. This finding indicated that the regenerated bone marrow was of donor origin. He fared well until the 56th post-transplant day when papilledema of the left optic disc was noted. Bone marrow examination did not show leukemia blasts at this time. X-ray therapy (600 rad) was delivered to the left eye. On the 112th day after the graft, his WBC count rose to 175,000/mm^3 with 82% blasts. Bone marrow examination confirmed the relapse. The cells were slightly positive for PAS and negative for Sudan black. Although palliative treatment with vincristine, prednisone, 6-mercaptopurine, and methotrexate was given for the next 4 months, leukemia cells appeared in the spinal fluid, and lymphoblasts persisted at low levels in the peripheral blood. Two months later (Sept. 79), the WBC count rose to 138,000/mm^3, of which 88% were blasts. The boy died of leukemia shortly thereafter, 8 months after the bone marrow graft.

MATERIALS AND METHODS

Studies were performed on bone marrow and/or peripheral blood which were obtained at diagnosis, during relapses, and in remission.

Cell marker studies.—Lymphoid cells including leukemia cells were separated on a Ficoll–metrizoate gradient (*12, 13*) and used in the following assays: T-cell markers: 1) E-rosettes (E^+). The spontaneous rosette formation technique of Jondal et al. (*14*) was used with a minor modification as described previously (*15*). When leukemia cells were tested on two occasions during the relapse after bone marrow transplantation, E-rosettes were assayed after incubation of leukemia cells with SRBC at 4, 25, and 37°C for 1 hour or longer. After leukemia cells were mixed with SRBC and incubated at 37°C in 5% CO_2 for 10 minutes, this cell suspension was divided into four aliquots and treated in the following manner. Three aliquots were first centrifuged at 200×*g* for 5 minutes and incubated at 4, 25, and 37°C. The fourth aliquot was not centrifuged but sedimented by gravity at 25°C. Incubation time of these aliquots was 1 hour or longer.

2) Indirect membrane immunofluorescence with the use of anti-T-cell serum. Rabbit antiserum specific to T-cell antigen (T-LCL) (*16*) was prepared and characterized according to methods previously reported. Using this antiserum as a primary reagent and fluorescein-conjugated goat anti-rabbit globulin serum as the secondary reagent, we performed indirect membrane immunofluorescence for detection of membrane antigen. The T-LCL antigen is expressed on normal T-lymphocytes, thymocytes, and T-cell leukemia–lymphoma cells (*17*).

B-cell markers: 1) Direct immunofluorescence for sIg. The method of Grey et al. (*18*) was used. Fluorescein-conjugated goat anti-human immunoglobulins (polyvalent and monovalent for γ, α, μ, δ, ε, κ, and λ (Meloy Laboratories Inc., Springfield, Va.) and fluorescein-conjugated $F(ab')_2$ fragments of anti-human IgG, IgM, and IgA (Cappel Laboratories, Inc., Cochranville, Pa.) were used as the reagents.

2) Detection of Fc receptor. *a*) Heat-aggregated human IgG. Fc receptors were detected by fluorescein-conjugated heat-aggregated IgG prepared by the method described by Dickler and Kunkel (*19*). *b*) EA rosettes. Rosette formation with bovine EA complex (*20*) was used.

3) Detection of complement receptor by EAC rosettes. Rosette formation with bovine EAC complex (*21*) was used.

Detection of Ia-like B-cell-associated (gp28,30) antigens.—Rabbit antiserum specific to Ia-like gp28,30 antigen (Ia-like) was prepared and characterized by the method described by Schlossman et al. (*22*). Indirect membrane immunofluorescence was used for detection of this antigen. This Ia-like antigen is expressed on normal peripheral B-lymphocytes, B-cell leukemia–lymphoma cells, cells from non-T-cell, non-B-cell leukemia (common ALL), and most acute myelocytic leukemia and CML in blast crisis (*17*).

cIg.—Cells were tested for cIg by means of the method described previously (*23*).

Latex phagocytosis.—Leukemia cells were incubated with a latex particle suspension (1:100, size 0.81 μm) (Difco Laboratories, Detroit, Mich.) as described by Schmidt and Douglas (*24*) with a minor modification.

Combined test for T-cell, B-cell, and monocytic markers in the same cells.—Tests for the three markers (E-rosettes, sIg, and phagocytosis) were done sequentially on the same cells. Cells were first incubated with latex particles, washed, and incubated with fluorescein-conjugated antisera to human immunoglobulins, washed, and finally incubated with SRBC for detection of rosette-forming cells. Individual cells were then examined alternately under phase contrast and fluorescein illumination by UV light for detection of latex particle and both T-marker and B-marker presence on the same cells.

Common form of ALL antigen.—Rabbit antiserum specific to the common form of ALL antigen (common ALL) was prepared and characterized by the method described by Greaves et al. (*25*).

Cytogenetics.—Chromosome studies were done on bone marrow processed by a direct preparative technique and on peripheral blood cultured for 24 hours without mitogen (*26*). Slides were prepared by the air-drying technique and G banded. This quality of the preparations did not permit complete characterization of the abnormal karyotypes, but aberrant "marker" chromosomes were sufficiently distinctive to be recognized readily in different metaphases.

RESULTS

Cell Membrane Phenotypes

Membrane phenotypes were studied at diagnosis, on the 16th day of induction therapy when leukemia cells reappeared, and on two occasions (April 79, Sept. 79) during a 6-month-long relapse after bone marrow transplantation.

Results are shown in table 1. At diagnosis 27% of leukemia cells were E$^+$, and no cells were positive for sIg. On the 16th day of induction, leukemia cells appeared more monoblastic than lymphoblastic. Fifty percent of these cells were E$^+$ and 80% were positive for sIg (tested with polyvalent antiserum). When tested with monospecific antisera, 100% of cells were positive for λ-light chain only. Also, 50% of these cells phagocytized latex particles (fig. 1). When the procedures were combined (*see* "Materials and Methods"), six populations of leukemia cells were observed: 1) E$^+$ cells, 21%; 2) E$^+$ cells with positive phagocytosis, 15% (fig. 1); 3) sIg$^+$ cells, 16%; 4) sIg$^+$ with phagocytosis, 33%; 5) çells with phagocytosis only, 7%; and 6) cells with no markers, 8%. With the combined procedures, sIg$^+$ cells were 49% (16 + 33%) compared with 80% by a single test (table 1), probably because combined tests were done on cells stored at 4°C for 2 days, and the three steps of analysis tended to lower the percentage of positive cells.

Shortly after the post-transplant relapse (April 79), there were 48% E$^+$ cells and no cells with sIg or positive EA rosettes. Less than 1% of the cells were positive for T-LCL antigen. All were positive for Ia-like gp28,30 antigen, and 30% were positive for common ALL antigen. No cells were positive for cIg or phagocytized latex particles.

During the terminal stage (Sept. 79), E$^+$ cells ranged from 29 to 44%. T-LCL antigen-positive cells were 0.8%. Twenty-five to 30% of the cells were positive for sIg of lambda light chain. Some cells were weakly positive for μ-heavy chain. There were 10–15% of cells with Fc receptors demonstrated by EA rosettes and heat-aggregated IgG. EAC rosette-positive cells ranged from 2.3 to 15%. No cells phagocytized latex particles. All cells were negative for cIg. When the

procedures were combined, four populations of cells were observed: 1) E^+ cells, 19%; 2) E^+ and sIg^+ cells, 8%; 3) sIg^+ cells, 28%; 4) cells with no markers, 45%.

Cytogenetic Studies

Chromosome studies were done twice during the relapse after transplantation (April 79, Sept. 79) (table 1).

During the first relapse, material for study was obtained from blood (cultured for 24 hr without mitogen) and marrow. Twenty-one cells were counted from the blood: 7 were normal, and the remaining 14 metaphases had 46 chromosomes but showed multiple abnormalities. These included at least eight different aberrant marker chromosomes. The three most conspicuous markers indicated two major sublines: five metaphases contained marker 1, and nine metaphases contained markers 2 and 3. Marker 1 (M 1) was a large B-type chromosome, apparently a $5q^+$ (fig. 2A). Markers 2 and 3 (M 2, M 3) were large D-type chromosomes, with different banding patterns, whose origins could not be determined (fig. 2B). Every abnormal metaphase contained either M 1 or M 2 and M 3, and there was enough sharing of other aberrant chromosomes to indicate that these two populations presented sublines within the same neoplastic clone. Among the shared markers was an apparent $17p^-$ and a smaller abnormal chromosome with a similar banding pattern (figs. 2A, 2B).

In the bone marrow, 23 cells were counted: 9 were normal, and 14 metaphases were from the M 1 subline. No cells of the M 2, M 3 line were observed in the marrow.

In the terminal stage, 33 metaphases were obtained from blood cultures grown for 24 hours without mitogen. All were abnormal: 24 of the M 1 line, and 9 of the M 2, M 3 line. Some of the cells in the M 1 line now had 47 chromosomes, suggesting continuing evolution.

DISCUSSION

In this patient, different membrane phenotypes on the neoplastic cells were detected during the course of disease. If E-rosette formation at 4, 20, and 37°C are considered to represent T-cells, and E-rosettes at 37°C (*27*) and at 25°C by sedimentation are lymphoblasts with T-cell characteristics, then after transplantation more than 25% of this patient's leukemia cells retained T-cell markers throughout relapse. T-cell antigen (T-LCL) tested only in post-transplant relapse was not detected. Expression of T-antigen has been shown to precede that of SRBC receptor (E-rosette formation) during T-lymphocyte development (*28–32*). Some forms of lymphoblastic leukemia appear to represent cells arrested in a stage of development characterized by the expression of T-antigens but not SRBC receptors (*29*). Conversely, leukemia cells with a reversed expression of these markers have not been reported. Since T-cell antigen was not tested before the transplantation, we do not have an explanation for our finding of the reversed expression. During the first relapse after the graft, cells were negative for sIg and EA rosettes, and less than 1% were positive for EAC rosettes, indicating absence of the commonly recognized B-cell markers. However, Ia antigens were positive. In the terminal stage, Ia antigens were detected again and so were the other B-cell markers (sIg, Fc receptors, and EAC rosettes). Ia antigens on both occasions could have represented early lymphoid cell lines or stem cells common to lymphoid and granulocytic cell lines rather than B-cells. Another possibility is that the other B-cell markers except Ia antigen were selectively lost during the first relapse.

The monocyte marker used was the phagocytosis of latex particles by neoplastic cells and was detected only on one occasion when the cells morphologically also appeared more monoblastic than lymphoblastic. Fifty percent of cells showed phagocytosis, and one-third of these were also sIg^+, the remaining two-thirds were E^+ (fig. 1), and only a few were without either E^+ or sIg^+ markers (table 1). There was no cell with all three markers. We do not know whether the three-step procedures with multiple washing and handling of cells caused the loss of one or two markers or whether there was indeed no such cell. Nonetheless, this observation suggested that the neoplastic cells probably originated from a cell line that could express both lymphoid and monocytic characteristics.

Taking these observations together, the patient showed three types of surface markers throughout his course of leukemia: T-cell at diagnosis, T-, B-, and monocytic markers during the initial induction therapy, T-cell in the first relapse following the bone marrow transplantation, and T- and B-cells in the terminal stage. Occasionally, there were cells with double markers, which suggested that they were derived from a single common cell line.

Further evidence for this hypothesis is provided by the cytogenetic studies that were done during the post-transplantation relapse period. Two major abnormal sublines were detected in the cells studied. Both populations had multiple rearrangements, presumably from the large doses of radiation and chemotherapy preceding transplantation, but there was enough sharing of abnormal marker chromosomes between the sublines to indicate that they were from a common origin, with different proportions in the blood and bone marrow at different stages.

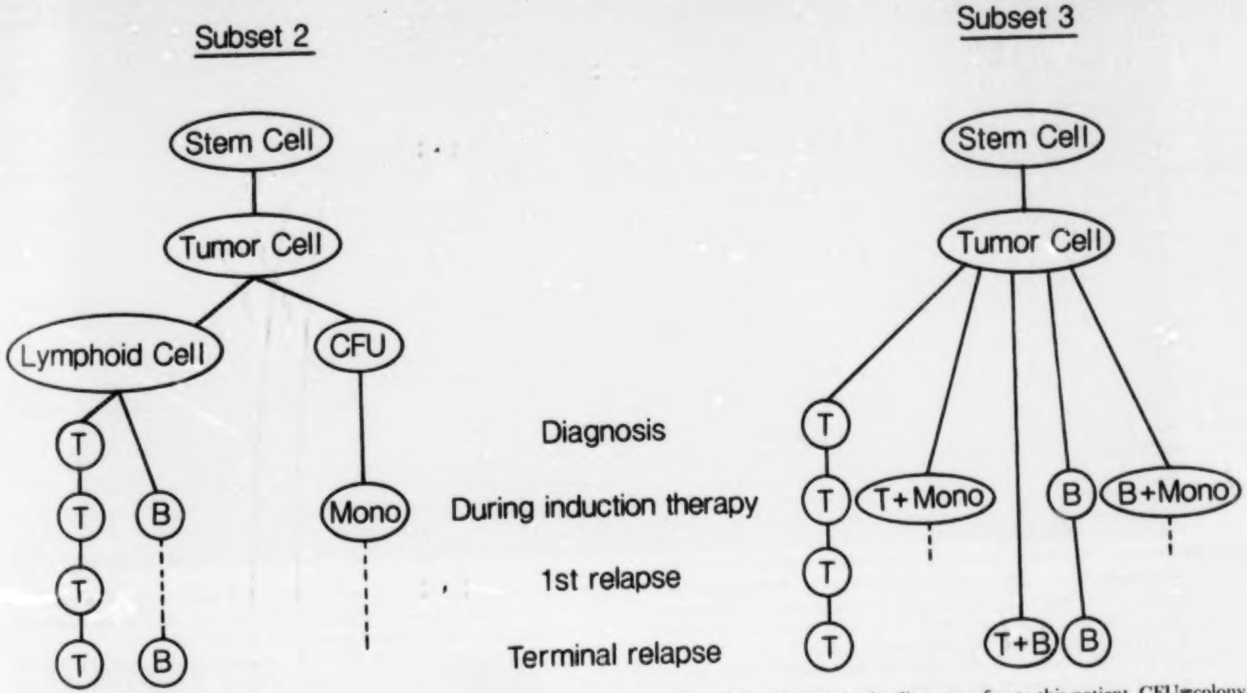
It is difficult to compare the chromosome data with the membrane marker studies done at various times, because there are only two time points in common. However, it may be significant that bone marrow cells from the first relapse post transplantation showed T-cell characteristics and that cytogenetically only one of two major abnormal sublines (subline 1) was found in the marrow at that time. When blood was studied in the terminal stage just prior to death, however, there was a mixture of cells with T- and B-cell characteristics, and the chromosome data indicated the presence in the blood of both major sublines. It is tempting to speculate that the cells identified cytogenetically as subline 1 had T-cell characteristics and that subline 2 had B-cell properties.

The results of this study support the view that as clonal evolution occurs during the clinical and biological progression of a malignant disease, more than one subpopulation may develop and coexist within the neoplasm. Such subpopulations were distinguishable in our patient by morphology, membrane phenotype, and genotype. A possible pattern for the clonal expression of leukemia cells in this case is illustrated in table 2.

This phenomenon has been reported in some patients

TABLE 2.—*Proposed clonal expression of leukemia cells*

Specification	Diagnosis, marrow	Induction, marrow	First relapse, marrow	Terminal stage, blood
Apparent cell types	T-cell	T-cell, B-cell monocyte	T-cell	T-cell, B-cell
Surface markers	E^+, sIg^-	E^+, sIg^+, phagocytosis$^+$	E^+, sIg^-, phagocytosis$^-$	E^+, sIg^+, phagocytosis$^-$
Chromosomes	Not done	Not done	Subline 1	Sublines 1, 2



TEXT-FIGURE 1.—Proposed subsets of acute leukemia. Subset 1 is described in the text. Clinical course in the diagram refers to this patient. CFU=colony-forming unit.

with CML and in rare patients with ALL (*33–36*). Recently, we have observed 2 more patients with ALL who changed membrane phenotypes from diagnosis to relapse. Apparently, drug-resistant subclones within a leukemia cell clone appear and sometimes dominate in the patient's bone marrow tissue and peripheral blood after the initially dominant drug-sensitive subclones of blast cells disappear. The clinical course of this particular patient was marked by poor responses to a variety of chemotherapy regimens. A successful bone marrow transplant was performed, but leukemia recurred. Since the donor was the same sex as the patient, we cannot determine whether or not the recurrent leukemia was the same as the original one, but surface markers suggest that it was the original leukemia that recurred. It has been shown that more than 95% of the observed post-transplantation relapses have been in host-type cells, presumably the original leukemia clone (*37*).

These results lead us to propose the hypothesis that there are subsets in childhood leukemia: 1) Acute leukemia originating from a lymphoid cell lineage and expressed as a single end cell of a lymphoid line, such as T-cell, B-cell, or null cell; 2) Acute leukemia originating from a stem cell and expressed as a mixture of different end cells that carry one marker in each cell, such as T-cells, B-cells, or monocytes (text-fig. 1); and 3) acute leukemia originating from a stem cell but having mixed characteristics of T-cells, B-cells, or monocytes in the same cells (text-fig. 1).

This case would belong to the last hypothetical subset (subset 3 in text-fig. 1). At diagnosis and during the first relapse after bone marrow transplantation, only T-cell characteristics were expressed, whereas during the induction period and the terminal stage, there were cells with mixed markers in the same cells. The clinical evolution of our patient indicates that if he was, in fact, an example of one of the two postulated subgroups, management by ordinary or even extraordinary means will prove to be very difficult.

Coproduction of Carcinoembryonic Antigen and Nonspecific Cross-Reacting Antigen by a Continuous Cell Line From a Human Pancreatic Tumor [1,2]

Masahide Kuroki,[3] **Sadanori Ichiki,**[3] **Motomu Kuroki,**[3] *and* **Yuji Matsuoka**[3,4,5]

ABSTRACT—A simultaneous production of nonspecific cross-reacting antigen (NCA) and carcinoembryonic antigen (CEA) by the same individual cells of an established human pancreatic cell line (QGP-1) was demonstrated by the immunoperoxidase method. Kinetics of cell proliferation and production of CEA and NCA were analyzed, and active synthesis of both antigens was found to be accompanied with the active proliferation of cultured cells. Both antigens in culture medium were purified by immunoadsorption and gel filtration. Immunochemical studies confirmed that CEA and NCA produced by the QGP-1 cells had properties identical to those of authentic CEA derived from metastatic colorectal carcinoma and to those of NCA from normal lungs, respectively.—JNCI 1982; 69:401–408.

Although the cancer specificity of CEA is, at present, rather controversial, its clinical usefulness is being widely accepted, especially in monitoring the response to therapy in cancer patients with elevated serum levels of CEA (*1, 2*). From the basic oncologic point of view, CEA is one of the most interesting glycoprotein antigens because the ontogenic and oncologic molecular differentiation process may be traced by the comparative structural analyses of CEA and related antigens in fetal tissues and in normal adult tissues or secretions (*3–5*). In this context, a number of CEA-related antigens in normal tissues have become significant (*6–9*). Among them, NCA (*10*), which is also known as normal glycoprotein [NGP (*11*)], glycoprotein related to CEA [CEX (*12*) and CCEA-2 (*13*)], and colon carcinoma antigen-III [CCA-III (*14*)], seems to be very important because this antigen is frequently detected in malignant tissues as well as normal tissues and has been reported to have a partial identity with CEA chemically and antigenically (*10, 15*). The NCA has been detected in normal blood granulocytes and macrophages of mesodermal origin (*16, 17*), but a controversy exists as to whether the epithelial cells of entodermal origin produced NCA or not, though some data suggested that the entodermal epithelial cells also produced NCA as well as CEA (*18*).

Thus the established CEA-producing cell lines seem to be of great significance for investigation of the mechanism of CEA expression by cancer cells and for understanding the biologic role of CEA (*19–25*). Although there are some suggestions that several CEA-producing cell lines also produced the NCA molecules (*26–28*), whether the same individual cells simultaneously produce both the CEA and NCA molecules or not remains to be determined. We investigated, as described herein, an established cell line from a human pancreatic tumor and found that this cell line coproduced the CEA and NCA molecules in the same cells, each having the immunochemical properties identical to those of CEA from colon tumors and of NCA from normal lungs.

MATERIALS AND METHODS

Cell Culture.—The human pancreatic cancer cell line QGP-1 was initially developed by Dr. Kaku at Kyushu Cancer Center, Fukuoka. It was originally established from a tumor mass surgically obtained from a 61-year-old Japanese male who had a circulating plasma CEA level of 1,369 ng/ml (measured by the CEA-Roche kit). By histologic examination, the cells were determined to be of islet cell origin. The characteristics of QGP-1 cells, such as morphology, biologic features, and CEA synthesis, have been outlined elsewhere (*29*). We received this cell line in 1979. The cells were maintained as monolayer cultures in RPMI-1640 medium supplemented with 5% fetal bovine serum (GIBCO, Grand Island, N.Y.), 5% newborn calf serum (GIBCO), 10^5 U penicillin/ml, and 100 µg streptomycin/ml. Confluent cell monolayers were passaged by treatment with trypsin–EDTA solution (0.25% trypsin and 0.075% EDTA in 0.1 *M* phosphate-buffered saline). All cultures were gassed with 5% CO_2 in air and incubated at 37°C.

Reference CEA and NCA preparations.—Reference CEA was prepared from metastatic liver tumors from colorectal cancer by use of a purification procedure described earlier (*30, 31*). NCA was purified from pooled normal human lungs by combination of an affinity chromatography on immunoadsorbent and gel filtration as described in (*9*). The CEA and NCA preparations contained practically pure antigens as demonstrated by immunoelectrophoresis and by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (*9*).

ABBREVIATIONS USED: CEA=carcinoembryonic antigen; Go-a-CEA=goat anti-CEA antiserum; NCA=nonspecific cross-reacting antigen; Go-a-NCA=goat anti-NCA antiserum; Q-CEA=CEA produced by QGP-1 cells; Q-NCA=NCA produced by QGP-1 cells; R-a-CEA=rabbit anti-CEA antiserum; R-a-NCA=rabbit anti-NCA antiserum; R-a-Q-CEA=rabbit anti-Q-CEA antiserum; R-a-Q-NCA=rabbit anti-Q-NCA antiserum.

[5] We thank Dr. M. Kaku, Kyushu Cancer Center, Fukuoka, Japan, for supplying the QGP-1 cell line; Dr. M. Kikuchi, School of Medicine, Fukuoka University, Dr. A. Horie, School of Medicine, University of Occupational and Environmental Health, Kitakyushu, Japan, and Dr. Y. Katsuta, Kyushu Cancer Center, for their kind supply of cancerous and noncancerous materials; Miss M. Kishimoto and Miss R. Iida, School of Medicine, Fukuoka University, for expert technical assistance; Dr. Y. Yagi, Nippon Roche Research Center, for reviewing the manuscript; and Miss N. Kawakami for typing the manuscript.

Antisera.—Two anti-CEA preparations were used in this study. Go-a-CEA and R-a-CEA against a preparation of CEA from tumor tissue were prepared as described previously (*31*). Go-a-CEA was specifically purified by adsorption to CEA–Sepharose 4B (*see below*) and by elution with 0.175 *M* glycine–HCl buffer (pH 2.8). The purified antibody preparation was used without further absorption or after complete absorption with NCA. An IgG-rich fraction of R-a-CEA obtained by salting out with 40% saturation of $(NH_4)_2SO_4$ was completely absorbed with NCA–Sepharose 4B and was used for the immunoperoxidase staining.

Go-a-NCA and R-a-NCA against lung NCA were obtained as described previously (*32*). Go-a-NCA was specifically purified by adsorption to and elution from NCA–Sepharose 4B. The purified antibody preparation was used after complete absorption with CEA. An IgG-rich fraction of R-a-NCA was completely absorbed with CEA–Sepharose 4B and used for the immunoperoxidase staining.

An antiserum against the CEA produced by QGP-1 cells (Q-CEA) (*see below*) was prepared in a rabbit that was immunized twice at five weekly intervals, each time with 200 μg of partially purified Q-CEA in complete Freund's adjuvant (Difco Laboratories, Detroit, Mich.). This antiserum was designated R-a-Q-CEA. An antiserum against the NCA produced by QGP-1 cells (Q-NCA) (*see below*) was raised as mentioned above, each time with 100 μg of partially purified Q-NCA and designated R-a-Q-NCA. R-a-Q-CEA and R-a-Q-NCA were used after absorption with fetal bovine serum and newborn calf serum.

We prepared a goat anti-rabbit IgG antiserum by immunizing with rabbit IgG purified by salting out with 40% $(NH_4)_2SO_4$ and by performing ion-exchange chromatography on DEAE–cellulose. A rabbit antiperoxidase antiserum was obtained by immunization with purified horse-radish peroxidase (type IV; Sigma Chemical Co., St. Louis, Mo.).

Antigen and antibody adsorbents.—Purified CEA and NCA were coupled with CNBr-activated Sepharose 4B (10 mg/g dry gel; Pharmacia Fine Chemicals AB, Uppsala, Sweden) according to the manufacturer's instructions.

Go-a-CEA specifically purified by CEA–Sepharose 4B was conjugated to CNBr-activated Sepharose 4B (10 mg/g dry gel) and used for specific purification of the antigens in QGP-1 culture media.

Immunoperoxidase staining.—We applied an unlabeled antibody enzyme method (*33*) to identify the CEA- or NCA-producing cells. Packed cells obtained from confluent culture were fixed in 10% buffered Formalin (pH 7.4) and embedded in paraffin by the usual techniques. Paraffin sections (2 μm) were treated with xylene and graded ethanol solution and finally with 0.05 *M* Tris–saline (pH 7.6). Serial sections were used to determine whether CEA and NCA are produced by the same cells or not.

Staining procedures were as follows: 1) We incubated the sections in 0.3% hydrogen peroxide in methanol to block endogenous peroxidase. 2) We added goat serum diluted twentyfold to the sections for 30 minutes to reduce nonspecific background staining. 3) We applied R-a-CEA absorbed with NCA, R-a-NCA absorbed with CEA, or control serum (each diluted 1:100) to the sections for 30 minutes. 4) We included goat anti-rabbit IgG (diluted 1:50) to the sections for 30 minutes. 5) We applied horse-radish peroxidase–rabbit antiperoxidase complex, which was synthesized according to the instruction of Sternberger et al. (*33*), to the sections for 30 minutes. 6) We effected 3,3′-diaminobenzidine (0.05%) reaction in the presence of 0.05% hydrogen peroxide for 5 minutes. All incubation steps were performed at 37°C, and washings after incubation were performed with Tris buffer. In these experiments, we always used in parallel for the control serum the normal rabbit serum, R-a-CEA absorbed with CEA, or R-a-NCA absorbed with NCA. The sections were finally counterstained with hematoxylin for 10 minutes, dehydrated in graded ethanol solutions and xylene, and mounted in Permount (Fisher Scientific Co., Fair Lawn, N.J.)

Gel filtrations.—Gel filtrations were performed with 0.05 *M* sodium phosphate buffer (pH 5.2).

Radioimmunoassay.—We estimated CEA in spent culture medium and in Sephadex G-200 column fractions by using previously described sandwich-type solid-phase methods (*32*). In this system NCA showed a negligible reactivity (10,000 ng of NCA corresponded to 3 ng of CEA). NCA was also determined by a similar method with the use of Go-a-NCA absorbed with CEA. In this system, 10,000 ng CEA gave a reaction equivalent to only 0.5 ng NCA. Fresh culture medium gave no reaction by these two assay systems.

Immunoelectrophoresis and immunodiffusion tests.—Immunoelectrophoresis and microscale immunodiffusion tests were performed in 1.2% agarose layer as described in (*31*).

RESULTS

Immunohistochemical Studies

The QGP-1 cells harvested by treatment with trypsin–EDTA solution are morphologically heterogenous and can be roughly categorized into two types: small cells and large cells (fig. 1). The large cells were not the cells spread after death since most of large cells were found to exclude trypan blue dye as did the small ones. Interrelation between these two types of cells is unclear at present. When the serial sections of packed QGP-1 cells were examined by the immunoperoxidase method, the cytoplasm of almost all the cells was stained diffusely or granularly both with specific R-a-CEA and with specific R-a-NCA (figs. 1A, 1B), though the staining of the large cells was generally rather faint. Obviously, the same individual cell was stained with both antibody reagents. This clearly indicated that both CEA and NCA were present in the cytoplasm of the same cells. No positive staining of the nuclei was observed by examination of the sections just before counterstaining with hematoxylin. None of the QGP-1 cells were stained with any of the control sera: normal rabbit serum, R-a-CEA absorbed with CEA, or R-a-NCA absorbed with NCA, confirming the immunologic specificity of the staining.

Growth Rate and Kinetics of CEA and NCA Production

To determine the growth rate and the output of Q-CEA and Q-NCA, 1.4×10^5 cells were seeded into each of 30 petri dishes (35 mm in diameter) containing 2 ml of nutrient medium. At intervals of 2 or 3 days, all the cells and spent culture medium of three dishes were individually harvested for the ensuing 14 days, and the average cell number per dish and viability at a given culture period were counted by trypan blue dye exclusion test with the use of a hemacytometer. The concentrations of CEA and NCA in spent culture medium of each dish were separately estimated by radioimmunoassay, and the average antigen concentrations in medium at a given culture period were calculated. No fresh medium was added to the cultures during the course of the experiment.

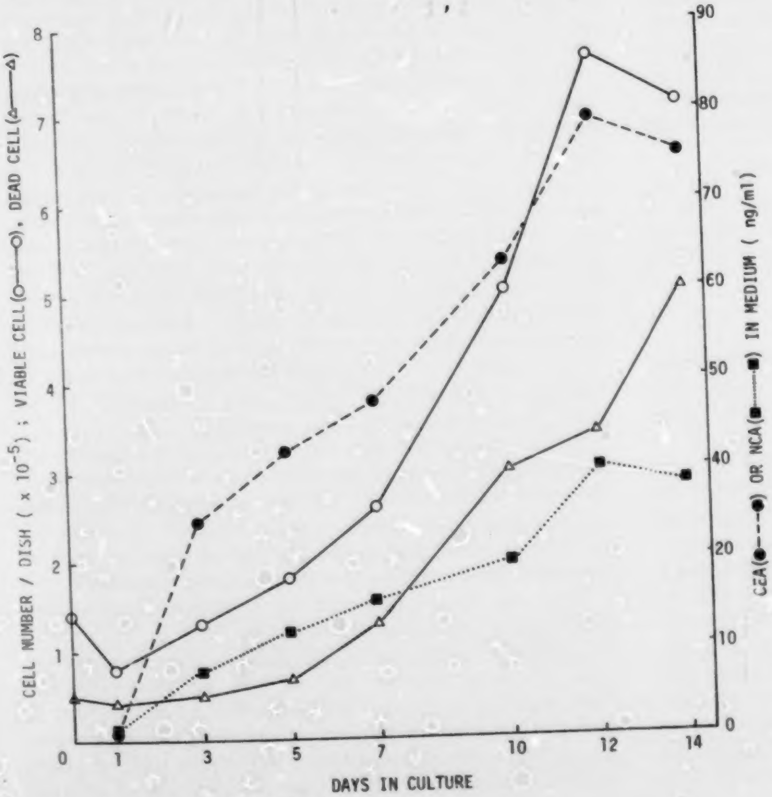
As can be seen in text-figure 1, after 1-day lag phase, the QGP-1 cells started to proliferate with the doubling time of about 3.5 days and reached confluence at day 12 of culture. Both CEA and NCA also started to accumulate in the medium after 1-day lag phase and kept increasing up to culture day 12 when the cells stopped proliferating (text-fig. 1). The concentrations of both CEA and NCA in medium accumulated by day 7 of culture were 37.7 and 15.7 ng/ml, respectively.

Isolation of CEA and NCA From Spent Culture Medium of QGP-1 Cells

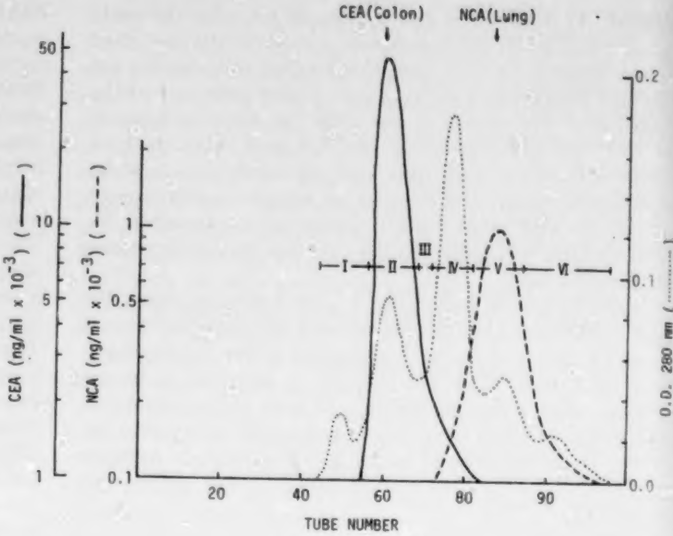
We tried to isolate CEA and NCA from spent culture medium by immunoadsorption and gel filtration. The perchloric acid extraction technique for precipitation of the protein, a technique frequently employed for the purification of CEA or CEA-related antigens, was not used in this study in order to minimize the loss of antigens. About 7.5 liters of spent medium of the QGP-1 cell line was collected, filtered through a 1.2-μm Millipore filter, and concentrated about fortyfold by pervaporation. The antigens in the concentrated medium (≈180 ml) were drawn into and eluted from the Go-a-CEA (not absorbed with NCA) adsorbent containing about 10 mg of purified antibody. The eluate was concentrated and applied to a Sephadex G-200 column. The elution profile is shown in text-figure 2. The major peak of optical density at 280 nm was due primarily to calf serum proteins contaminating the eluate. In fraction II, we detected the antigen reactive with specific anti-CEA antibody. The NCA activity was detected in fraction V. The concentrated fraction II was chromatographed on another Sephadex G-200 column. The antigen with CEA activity was eluted from the column as a single peak and designated Q-CEA. The antigen with NCA activity in fraction V was further chromatographed on a Sephadex G-200 column and eluted in a single peak and designated Q-NCA. The elution position of Q-CEA or Q-NCA on the Sephadex G-200 column was identical with that of reference CEA or NCA, respectively (text-fig. 2).

Immunochemical Studies of the Purified Q-CEA and Q-NCA Preparations

As can be seen in figure 2A, the precipitate line of Q-CEA with R-a-CEA coalesced completely with that of CEA from



TEXT-FIGURE 1.—Growth rate of the QGP-1 cells at passage 12 after recovery from liquid nitrogen storage and kinetics of CEA and NCA production by these cells. QGP-1 cells, 1.4×10^5, were seeded into 35-mm petri dishes with 2 ml medium, and then at indicated times the cell number and viability were estimated by a hemacytometer, and the CEA or NCA activity in supernatants of the dishes was determined by radioimmunoassay (*see text*).



TEXT-FIGURE 2.—Sephadex G-200 chromatography of the eluate from an anti-CEA adsorbent. Sample (1.2 ml) was applied to the column (1.7×100.0 cm). The effluent was collected in 1.5-ml portions and combined as indicated. Elution positions of colon carcinoma CEA and lung NCA are shown in references. O.D.=optical density.

tumor tissues. The precipitate line of Q-NCA fused partially with that of CEA and, in turn, the line of NCA fused partially with Q-CEA. The lines of NCA and Q-NCA with R-a-CEA coalesced completely with each other (fig. 2B). When tested with R-a-NCA absorbed with CEA, the line of Q-NCA also coalesced with that of NCA (fig. 2C). Furthermore, the immunologic reactivities of R-a-Q-CEA and R-a-Q-NCA were demonstrated to be the same as those of R-a-CEA and R-a-NCA, respectively (figs. 3A, 3B). These results indicated that antigenically Q-CEA was indistinguishable from CEA from tumor tissues, that Q-NCA was antigenically identical with NCA from lung, and that Q-NCA had a distinctive determinant (NCA distinctive determinant) in addition to the NCA common determinant as well as did authentic NCA (*9*, *10*, *12*).

The immunoelectrophoretic patterns of Q-CEA and Q-NCA are shown in figure 4 in comparison with those of CEA and NCA. No difference in mobility was observed between Q-CEA and CEA and between Q-NCA and NCA.

DISCUSSION

NCA was first identified in perchloric extracts of normal lung or spleen (*10*, *11*) as a glycoprotein antigen that partially shares antigenic determinants with CEA; NCA then was also found in normal colon mucosa (*18*) and in normal sera (*34*). NCA has also been frequently seen in association with CEA in the tumor tissues (*12*, *18*). In addition, NCA was found to be a normal constituent of blood granulocytes and macrophages (*16*, *17*), which leads to the suggestion that the presence of NCA in the tumor tissues is a result of infiltration of granulocytes due to inflammatory process in the tissues. However, several histologic examinations of the tissue samples revealed no correlation between the degree of granulocyte infiltration and concentration of NCA in the corresponding tissue extracts (*35*). The question has occurred, therefore, of whether or not NCA is also produced by the tumor cells themselves. In 1975, by using the immunofluorescence technique, von Kleist et al. (*27*) revealed that NCA was synthesized by a CEA-producing colon tumor cell line (HT-29). This finding was followed by a report (*28*) demonstrating the presence of NCA on the cells from this HT-29 cell line by means of the antibody-dependent, cell-mediated cytotoxicity assay. In addition, Heumann et al. (*36*) demonstrated that a colon carcinoma cell line produced NCA even after passage in nude mice. However, it has not been determined whether or not CEA and NCA are produced by the same cells, and no immunochemical characterization has been made about the NCA synthesized by the CEA-producing tumor cell line.

In the present study, the immunoperoxidase method clearly demonstrated that both CEA and NCA were synthesized by the same individual cells of pancreatic tumor origin (figs. 1A, 1B). A preliminary experiment with the use of the double-staining procedure by the respective antisera conjugated with two different fluorochromes (tetramethylrhodamine isothiocyanate and fluorescein isothiocyanate) also detected the CEA and NCA on the same cells of QGP-1 cell line (data not shown). To our knowledge, NCA has not yet been described on pancreatic tumor cell lines. NCA is frequently elevated also in the sera of patients with pancreatic tumor (*12*, *34*) and can be demonstrated easily in fetal pancreatic extracts (*37*). Hence its presence on the cultured pancreatic cells is not illogical.

Immunoperoxidase staining of the QGP-1 cells revealed the intracytoplasmic localization of both CEA and NCA. These findings are strong evidence favoring the idea of CEA or NCA being synthesized in the cytoplasm. Granular deposits may be related to the storage of CEA or NCA in distended ergastoplasmic cisternae of Golgi apparatus.

From the results obtained by a kinetic study of cell proliferation and antigen production (text-fig. 1), it seems clear that: 1) During the lag phase no antigens were synthesized, 2) the production rate of both antigens CEA and NCA was most active in the early period after seeding, 3) the active synthesis of antigens was observed during a period in which the cells also proliferate actively, 4) after cells have reached confluence neither active proliferation of cells nor active production of the antigens was observed and, therefore, 5) accumulation of the antigens in culture medium does not seem to be due to passive release of antigens from the dead or dying cells.

The production rate of CEA by QGP-1 cells is comparable to that reported for other CEA-producing cell lines such as HT-29 cells (*19*) and HRT-18 or HCT-8 cells (*20*). The rate of NCA production by QGP-1 cells was about the same as that of CEA production, on the molecular basis; but this may be variable depending on the nature of cell line established.

Immunochemical analyses indicate that Q-CEA and Q-NCA have antigenic and physicochemical properties identical to those of authentic colon carcinoma CEA and lung NCA, respectively. Q-NCA seems not to be simply a fragment of the CEA (Q-CEA) molecule since Q-NCA possessed a unique determinant identical to that of lung NCA, and there are enough immunologic and chemical differences proving that NCA and CEA are distinct molecules (*6, 15*). Shively et al. (*7*) have suggested that CEA and NCA were products of sister (or daughter) genes derived from a single primordial gene by replication and evolutionary divergence inasmuch as the similarity between the NH_2 terminal sequences of CEA and NCA was demonstrated (*15*). The fact that the Q-NCA having immunochemical properties similar to those of lung NCA was coproduced by the very CEA-producing cells suggests that these sister genes are simultaneously active in some tumor cells.

Further characterization of the QGP-1 cell line and chemical analyses of Q-CEA and Q-NCA produced by this line may help us to understand in what way CEA is related to the normal tissue component NCA.

Repair of Chromosome Damage Induced by X-Irradiation During G_2 Phase in a Line of Normal Human Fibroblasts and Its Malignant Derivative[1]

Ram Parshad,[2] Raymond Gantt,[3] Katherine K. Sanford,[3, 4] Gary M. Jones,[3] *and* Robert E. Tarone[5]

ABSTRACT—A line of normal human skin fibroblasts (KD) differed from its malignant derivative (HUT-14) in the extent of cytogenetic damage induced by X-irradiation during G_2 phase. Malignant cells had significantly more chromatid breaks and gaps after exposure to 25, 50, or 100 rad. On the assumption that each chromatid contains a single continuous DNA double helix, chromatid breaks would represent unrepaired DNA double-strand breaks; the gaps may represent single-strand breaks. Results from alkaline elution of cellular DNA immediately after irradiation showed that the normal and malignant cells in asynchronous population were equally sensitive to DNA single-strand breakage by X-irradiation. Caffeine or β-cytosine arabinoside (ara-C), inhibitors of DNA repair, when added directly following G_2 phase exposure, significantly increased the incidence of radiation-induced chromatid damage in the normal cells. In contrast, similar treatment of the malignant cells had little influence. Ara-C differed from caffeine in its effects; whereas both agents increased the frequency of chromatid breaks and gaps, only ara-C increased the frequency of gaps to the level observed in the irradiated malignant cells. Addition of catalase, which destroys H_2O_2, or mannitol, a scavenger of the derivative free hydroxyl radical (·OH), to the cultures of malignant cells before, during, and following irradiation significantly reduced the chromatid damage; and catalase prevented formation of chromatid gaps. The DNA damage induced by X-ray during G_2 phase in the normal KD cells was apparently repaired by a caffeine- and ara-C-sensitive mechanism(s) that was deficient or absent in their malignant derivatives.—JNCI 1982; 69:409–414.

Cytogenetic findings in recent years implicate chromosome DNA damage and deficient repair in the process of malignant neoplastic transformation. Cells from individuals predisposed to a high risk of cancer, such as those with xeroderma pigmentosum, ataxia telangiectasia, Fanconi's anemia, or Bloom's syndrome, show abnormally increased chromosome breakage on exposure to various DNA-damaging agents and/or are prone to spontaneous chromosome breaks in culture (*1*). Furthermore, such individuals may show an impaired capacity to repair DNA damage. In addition, both mouse and human cells transformed to malignant cells in culture show an increased incidence of chromatid breaks after exposure to fluorescent light, as compared with their normal counterparts (*2, 3*). This increased incidence results from an impaired capacity to repair DNA strand breaks [(*4*); Parshad R, Sanford KK, Jones GM, Tarone RE: Submitted for publication]. The extent of DNA repair is also influenced by the phase of the cell cycle at the time of exposure to the damaging agent. For example, both normal and malignant human cells showed comparable chromatid damage when exposed to light prior to S-phase, but only the malignant cells showed unrepaired chromatid breaks when exposed during the late S-G_2 period. These results imply a difference between normal and malignant cells in their capacity to repair light-induced damage, particularly when inflicted during late S-G_2. Because this light-induced damage is mediated through the intracellular generation of H_2O_2 and its derivative free hydroxyl radical (·OH) (*5, 6*), both of which are produced during X-irradiation (*7*), we compared in the present study the incidence of chromatid breaks following X-irradiation during G_2 phase in a line of normal human fibroblasts (KD) and its malignant derivative (HUT-14). By examining metaphase cells 1–1.5 hour after irradiation, we could be assured that the cells were in G_2 at the time of X-irradiation. In one set of experiments, catalase, which decomposes H_2O_2, and mannitol, an ·OH scavenger, were added to the cultures before, during, and after X-irradiation for evaluation of the extent of chromatid damage attributable to these two agents.

An increased incidence of chromatid breaks could result from an enhanced susceptibility to DNA damage or from an impaired capacity to repair such damage. Therefore, we also evaluated in asynchronous populations the relative susceptibility of the cells to DNA breakage by X-ray and the influence of inhibitors of DNA repair such as caffeine (*8*) and ara-C (*9*) on radiation-induced chromatid breaks.

MATERIALS AND METHODS

Cell culture, irradiation, and cytogenetic procedures.—A line of human skin fibroblasts (KD) and its malignant derivative (HUT-14) transformed in culture by 4-nitroquinoline 1-oxide were provided by Dr. T. Kakunaga, National Cancer Institute (*10*). Because the KD line is diploid and nontumorigenic, it is referred to as "normal" in this paper. Stock cultures were grown in Dulbecco's modified Eagle's minimum essential medium supplemented with 10% fetal bovine serum (Flow Laboratories, Inc., McLean, Va.) as described in (*3*). For chromosome studies, 0.5–1.0×10^5 cells in 2 ml medium were inoculated into Leighton tubes each containing a 9×50-mm cover slip (#1 thickness; Bellco Glass, Inc., Vineland, N.J.). After 48 hours of incubation at 37°C, cultures were irradiated by means of two Philips RT250

ABBREVIATION USED: ara-C=β-cytosine arabinoside.

opposing therapeutic 250-kV potential X-ray tubes operated at 235 kV, 15 mA, with 0.25-mm Cu and 0.55-mm Al filters (half-value layer, 0.9 mm Cu) and at a dose rate of 126 R/minute at 54-cm target distance. After irradiation, culture fluid was renewed within approximately 10–30 minutes, and 0.1 µg Colcemid/ml (GIBCO, Grand Island, N.Y.) was added for 1 hour either immediately or after 1- or 2-hour incubation, as indicated in the text. Caffeine, ara-C, catalase (Sigma Chemical Co., St. Louis, Mo.), and mannitol (Calbiochem-Behring Corp., La Jolla, Calif.) were added to the culture medium as described later. For chromosome analysis, the experimental and control cells were processed in situ on cover slips by techniques described (*11*). Chromosome analyses were made on randomized, coded preparations; four cultures were used for each variable. Only complete, well-spread metaphase cells were analyzed. The statistical analyses were based on both the number of chromatid breaks or gaps per cell and the percentage of cells showing these abnormalities. Abnormalities scored as breaks showed distinct dislocation and misalignment of the chromatid fragment, whereas gaps were achromatic lesions showing no dislocation.

In one experiment, normal and malignant cells were cocultivated by inoculation of 3×10^4 KD cells and 2×10^4 HUT-14 cells per Leighton tube; 48 hours later cultures were irradiated and processed as described above. The KD and HUT-14 metaphase cells were identified on the basis of chromosome numbers since KD cells are predominantly diploid (46 chromosomes) in contrast to subdiploid chromosome 43–45 in HUT-14.

In the experiment on the influence of 50 µg caffeine/ml on mitotic delay induced by X-irradiation, four cultures per variable were scanned for total number of metaphase cells. Mitotic inhibition was determined for postirradiation periods of 1.5 and 2 hours, during which time cells were exposed to caffeine. Cells were arrested in metaphase by Colcemid treatment for 1 hour before fixation. In the nonirradiated controls, 198 and 816 metaphase cells were enumerated in KD and HUT-14, respectively.

Technique for determination of irradiation-induced DNA strand breakage.—Cellular DNA size indicative of strand breakage was determined by the alkaline elution method of Kohn (*12*) with minor variations. In Kohn's method (with or without minor variation), the elution rate is dependent on the DNA strand length. (The higher the molecular weight, the slower the elution rate.) Cells of the two lines were prelabeled, one with [2-^{14}C]thymidine (15 nCi/ml) and the other with [*methyl*-^{3}H]thymidine (30 nCi/ml); cells were cocultivated in a T-25 flask (7.5×10^4 malignant and 1.5×10^5 normal cells). After 24 hours, the cells were chilled to 0°C, X-irradiated, and mechanically removed in 3 ml fresh medium. The cells were then placed on a polyvinyl chloride membrane (2-µm pore, BSWP02500; Millipore, Corp., Bedford, Mass.) and lysed with 20 m*M* EDTA (pH 10.2) containing 0.2% Sarkosyl (wt/vol) and 2 *M* NaCl. The DNA was fragmented with a burst of air from a syringe fitted to the filter holder (*13*) and eluted at a flow rate of 0.04 ml/minute with 20 m*M* EDTA (free-acid form) titrated to pH 12.2 with tetra-propylammonium hydroxide. Fractions were collected every 90 minutes for 18–20 hours, and the radioactivity remaining on the filter and in the filter holder was determined. The cells and DNA were shielded from light or exposed only to light through gold filters during culture, filtration, and elution.

RESULTS

X-ray-Induced Chromatid Damage in Normal and Malignant Human Cells

In the first posttreatment metaphase after X-irradiation of cells in G_2 phase, only two types of chromosome aberrations, chromatid breaks and gaps, were observed. In the normal cell population, cells entered metaphase only during the 1st hour after irradiation, whereas in the malignant cell population some cells were still entering metaphase even 3 hours after treatment. Thus the malignant cells, in contrast to the normal cells, did not show the distinct radiation-induced G_2 block or mitotic delay.

The malignant cells (HUT-14) had significantly more

None			200	0.010	0	200	0.055	0

[a] Number does not indicate total metaphase cells per variable (*see* Materials and Methods). No metaphase cell observed, —.

[b] Normal cells were predominantly diploid (46 chromosomes).

[c] Malignant cells were predominantly subdiploid (43–45 chromosomes).

[d] $P<10^{-4}$ and $P=0.003$ in comparisons of malignant vs. normal for chromatid breaks and gaps, respectively.

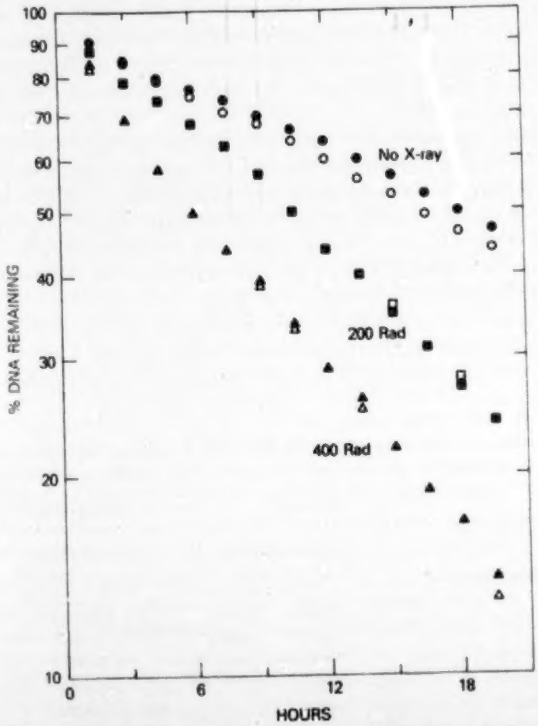
[e] $P<10^{-4}$ for increase in chromatid breaks with increasing radiation dose.

chromatid breaks than did their normal counterparts (KD) after exposure to 25, 50, or 100 rad ($P<10^{-4}$) and a slightly higher spontaneous chromatid breakage as seen in the unirradiated controls (table 1). They also showed a significant increase in chromatid breaks with increasing radiation dose ($P<10^{-4}$), whereas in the normal KD cells the increase was significant only with 100 rad ($P=0.05$). In addition, the malignant cells compared to the normal cells had increased frequencies of chromatid gaps following 25, 50, or 100 rad, although the increase was significant only at 100-rad exposure ($P=0.003$). These differential responses of normal and malignant cells to X-irradiation were further confirmed in a cocultivation experiment.

In certain experiments, the incubation period after irradiation was increased to allow additional time for repair of DNA damage (table 1). Periods of 1, 2, or 3 hours after 25 rad did not significantly alter the frequency of chromatid breaks or gaps in the malignant cells. However, after 100 rad chromatid breaks and gaps increased significantly at 2 hours of posttreatment as compared to 1 hour ($P<10^{-4}$ and $P=0.007$, respectively). No increase was observed during the 3d hour. As noted earlier, normal cells did not enter metaphase between 1 and 2 hours after treatment.

X-ray-Induced DNA Fragmentation and Repair in Normal and Malignant Cells

The initial susceptibility of normal as compared with malignant cells to X-ray-induced strand breaks was evaluated by determination of the relative molecular weights of DNA in the two cell populations immediately after irradiation. The elution rates of the DNA were essentially the same for both cell lines at each X-ray dose tested (text-fig. 1). These results indicated that irradiation caused an equivalent number of DNA strand breaks and that the two populations were similar in their susceptibility to irradiation as measured by DNA single-strand breaks.



TEXT-FIGURE 1.—Effect of X-ray irradiation on the alkaline elution rates of DNA from normal and malignant cells. *Open symbols* represent malignant cells; *closed symbols* represent normal cells. ○, ●, no X-ray; □, ■, 200 rad; △, ▲, 400 rad.

[c] Control and experimental cultures chilled on ice during irradiation and until medium renewal.

rapidly for both lines and after 30 minutes the elution rate was substantially slower; these results indicated that more than half the DNA strand breaks were repaired. By 3 hours the elution rates were essentially those of untreated cells. From the results with this technique, it appeared that the rates of repair of the X-ray-induced DNA single-strand breaks were similar.

Influence of Catalase and Mannitol on X-irradiation-Induced Chromatid Damage

Addition of catalase to the cultures of malignant cells before, during, and after irradiation produced a dose-related decrease in the frequency of chromatid breaks ($P=10^{-4}$) and chromatid gaps ($P<10^{-4}$) (table 2). At the highest dose of catalase, the frequency of breaks was still significantly greater than that in nonirradiated cells ($P=2\times10^{-4}$), whereas the frequency of gaps was identical to that in the nonirradiated controls.

Addition of mannitol before, during, and after irradiation was also associated with a dose-related decrease in the frequency of both chromatid breaks ($P=0.003$) and chromatid gaps ($P=0.03$) with no additional decrease after 10 m*M*. The frequencies of both breaks and gaps even at the highest dose of mannitol were significantly greater than those in the nonirradiated cells ($P<10^{-4}$ and $P=0.002$, respectively).

Influence of Inhibitors of DNA Repair on Chromatid Damage From X-irradiation in G₂

Caffeine had little influence on malignant cells with respect to chromatid breaks or gaps when added directly following irradiation and during Colcemid treatment. In contrast, similar treatment of normal cells with caffeine in two experiments significantly increased both chromatid breaks ($P=0.005$ and $P=0.030$) and chromatid gaps ($P=0.014$ and $P=0.002$) as compared with irradiated control cells (table 3). However, the levels attained in the caffeine-treated normal cells were less than those in the irradiated malignant cells.

Because caffeine is known to reduce the duration of X-ray-induced G₂ phase delay (14–17), the increase in irradiation-induced damage in the normal cells after caffeine treatment could result from a "breakthrough" of the G₂ block, allowing a shorter period available for DNA repair (*17*). However, addition of 50 µg caffeine/ml to the normal cells did not initiate a breakthrough since such addition did not increase the number of cells entering metaphase during the 2 hours after treatment (text-fig. 3). In contrast, caffeine did increase the number of metaphase cells in the malignant cell population.

TABLE 4.—*Influence of* 10^{-5} M *ara-C on X-ray-induced chromatid damage in normal and malignant cells during G₂ phase*

Treatment	Normal			Malignant		
	No. of cells studied	Average No. per cell		No. of cells studied	Average No. per cell	
		Chromatid breaks	Chromatid gaps		Chromatid breaks	Chromatid gaps
None	200	0.010	0	113	0.027	0.027
Ara-C	200	0.015	0	129	0.031	0
50 rad	200	0.010	0.010	150	0.573	0.140
50 rad + ara-C	185	0.065[a]	0.124[a]	115	0.548	0.122

[a] $P=0.009$ and $P=10^{-4}$ in comparison with untreated irradiated controls for chromatid breaks and gaps, respectively.

Like caffeine, ara-C significantly increased the frequency of X-ray-induced chromatid breaks and gaps in the normal cells ($P=0.009$ and $P=10^{-4}$, respectively) (table 4). The frequency of chromatid gaps was particularly enhanced by ara-C to a level comparable to that in the X-irradiated malignant cells. In the malignant cells, however, ara-C had no influence on the X-ray-induced chromatid breaks or gaps.

DISCUSSION

An extensive literature (*18–20*) details the cytogenetic effects of ionizing irradiation on mammalian cells in culture. The present study is unique in the comparison of the chromatid damage in normal cells and their malignant derivatives following X-irradiation exclusively in the G_2 phase of the cell cycle or within 1–1.5 hours of metaphase. X-irradiation is known to induce several types of lesions in DNA, including single- and double-strand breaks, cross-links, and endonuclease-sensitive sites, presumably representing base damage. On the assumption that each chromatid contains a single, continuous DNA double helix, chromatid breaks seen in the first metaphase following G_2 irradiation must represent unrepaired double-strand DNA breaks. These double-strand breaks could arise directly or indirectly as the result of repair processes (*4, 9, 19–22*). Achromatic lesions or gaps especially prevalent in cells irradiated in early prophase or late G_2 (*23*) may represent single-strand breaks (*20, 24, 25*). In the present study, the chromatid gaps induced in the malignant cells by X-irradiation during G_2 were completely prevented by addition of catalase before, during, and after irradiation. In the normal cells, the low incidence of gaps induced by X-irradiation during G_2 was significantly enhanced by addition of ara-C following irradiation. Ara-C has also been shown to increase the incidence of chromatid deletions in normal human lymphocytes X-irradiated during G_2 (*9*). It was suggested that ara-C molecules incorporated into the repair–replicating DNA distort the helix, prevent the polymerase from functioning, and inhibit repair of base damage (*9, 22*). In studies on the excision repair of UV-induced base damage in normal human fibroblasts, ara-C seemed to inhibit the rejoining of breaks formed by the endonuclease, probably through inhibition of polymerase activity (*26*). In accordance with these observations and interpretations, the chromatid gaps observed in the present study may result from incomplete excision repair of base damage produced by X-irradiation during G_2.

Although the malignant cells as compared with their normal counterparts have a slightly higher spontaneous chromatid breakage as seen in unirradiated control cells, they show significantly more chromatid breaks and gaps after X-irradiation during G_2. These findings confirm and extend our previous observations that malignant cells of either mouse or human origin develop more chromatid breaks than do their normal counterparts when exposed to fluorescent light during late S–G_2 [(*4*); Parshad R, Sanford KK, Jones GM, Tarone RE: Submitted for publication].

The increased incidence of chromatid damage in the malignant cells as compared with their normal counterparts could result from greater initial DNA damage by irradiation, from a decreased radiation-induced mitotic delay allowing less time for DNA repair (*16, 17*), or from an impaired capacity to repair the DNA damage. Our results from alkaline elution of DNA immediately after irradiation show that the malignant and normal cells are equally sensitive to DNA single-strand breakage by X-irradiation. From our results (table 1, text-fig. 3), the G_2 mitotic block induced by X-irradiation in both cell lines (although to a lesser extent in HUT-14) occurs somewhere between 1 and 2 hours before metaphase. Therefore, those cells that reached metaphase during the 1st hour after X-irradiation were in late G_2 and would not have been subject to the mitotic block since they would have passed the "transition point" (*27*) at the time of irradiation. Furthermore, if chromatid damage in the malignant cells results from inadequate time for DNA repair, a decreasing yield of chromatid damage would be expected in cells sampled at increasing postirradiation intervals. Such was not the case, and the incidence of both chromatid breaks and gaps was significantly increased at 2 and 3 hours post-irradiation.

Our results from use of inhibitors of DNA repair, caffeine and ara-C, suggest that the increased chromatid damage in the malignant cells results from an impaired capacity to repair radiation-induced DNA damage inflicted during G_2. Exposure of cells to caffeine directly following irradiation significantly increased the X-ray-induced chromatid damage in the normal cells but had little influence on the malignant cells. Because caffeine is also known to reduce the mitotic delay produced by irradiation, the increased chromatid damage in the normal cells could be interpreted as resulting from the shorter time available for repair (*14–17*). However, at the concentration used, caffeine did not influence the mitotic delay in the normal cells, although it did reduce this delay in the malignant cells. A role for caffeine in inhibiting DNA repair, other than daughter-strand repair, has not been established in eukaryotic cells; yet cytogenetic observations support the concept that caffeine inhibits repair of DNA damage inflicted by X-rays during G_2 or by fluorescent light during late S–G_2 [(*4, 28, 29*); Parshad R, Sanford KK, Jones GM, Tarone RE. Submitted for publication]. Like caffeine, ara-C added directly to cultures of normal cells following irradiation during G_2 significantly increased X-ray-induced chromatid breaks and gaps but had no influence on the malignant cells.

No difference in the rate or extent of repair of X-ray-induced DNA strand breaks could be detected by the alkaline elution technique. However, the alkaline elution technique measures repair of single-strand breaks, whereas the cytogenetic procedure measures unrepaired double-strand breaks after at least 1-hour incubation of cells, during which the repair of most single-strand breaks occurs even with doses of 400 rad (text-fig. 2). Some of the unrepaired double-strand breaks may result from incomplete, longer-term excision repair of base damage. Further, the alkaline elution technique was applied to asynchronous cell populations, whereas the cytogenetic analyses were limited to cells in G_2 at the time of irradiation. Finally, the sensitivity of the alkaline elution technique is insufficient to detect the level of unrepaired DNA double-strand breakage, (0.01–3.7

breaks/cell) observed by these cytogenetic procedures (*30*).

The present results indicate that the DNA damage induced by X-ray during G_2 in the normal KD cells is almost completely repaired by a mechanism(s) sensitive to caffeine and ara-C, whereas the malignant derivatives are deficient in this repair mechanism(s).

Role of Anchorage in the Expression of Tumorigenicity of Untransformed Mouse Cell Lines[1,2,3]

Robert S. Wells,[4] Evelyn W. Campbell,[5] Douglas E. Swartzendruber,[6] Lawrence M. Holland,[5] *and* Paul M. Kraemer[5,7,8]

ABSTRACT—Cultured mouse cells were tested for tumorigenicity in nude mice with both a conventional assay (injection of cell suspensions) and a new test involving implantation of cells grown on gelatin sponges. Sublines of Balb/3T3 cells, obtained from different sources, varied in their tumorigenic potential with either assay. One subline (A) formed distinctive precancerous nodules only in the sponge assay; these nodules often became progressive after a latent period of 3–4 months. However, suspensions of cells of this subline also caused tumors after a similar latent period, but no nodular phase preceded tumor formation. Another subline of Balb/3T3 (M) has failed to form tumors in either assay. The Balb/3T3 sublines did not differ in in vitro properties, such as low saturation density, failure to grow in methylcellulose, and monolayer morphology. A second experimental approach involved tests on nude BALB/c mouse-embryo fibroblasts at various passage levels. The cells were passaged from primary culture, through crisis, to heteroploid, established cell lines. Tumorigenicity was demonstrable earlier in the sponge assay, at which time in vitro parameters putatively associated with malignant behavior were unchanged. Possible relationships with the in vivo phenomenon of solid-surface sarcomagenesis are discussed.—JNCI 1982; 69:415–423.

Tumorigenicity studies in nude mice have been used to investigate the biological significance of in vitro cell transformation (*1–16*). Questions have arisen, however, concerning the methods commonly used to test cells for tumorigenic potential. For instance, Boone and Jacobs (*7*) and Boone (*17*) have shown that two commonly used untransformed mouse cell lines (Balb/3T3 and C3H/10T½) were tumorigenic if the cells were anchored to substrate (plastic platelets or glass beads) at the time of implantation. Using the same plastic platelet method, Boone et al. (*18*) also showed that freshly explanted adult connective tissue cells were tumorigenic after subculture in vitro. By contrast, the same type of cells was not tumorigenic when a conventional assay was used (injection of at least 10^6 cells in suspension).

The present report describes initial results with a tumorigenicity assay system that, like Boone's, provides anchorage for the cells. The system is based on the subcutaneous implantation into nude mice of Gelfoam sponge disks containing 10^4–10^5 growing cells. The system has a number of practical advantages and can be applied to the specific goal of investigating the role of anchorage in the expression of tumorigenic potential of untransformed cultured mouse cells. The role of anchorage is of interest because Boone's results suggest that anchorage to certain nonbiologic substrates (plastic and glass) exerts a tumor-promoting or tumor-initiating effect on mouse cells. Since routine tissue culture employs anchorage to these same substrates, a clearer understanding of the matter would influence the interpretation of studies of in vitro transformation by viruses, chemicals, or radiation. Clearly, spontaneous transformation of rodent cells in culture (*8*) is already a complicating feature of these systems.

MATERIALS AND METHODS

Cells.—Subline A of Balb/3T3 cells was obtained from the American Type Culture Collection, Rockville, Md.; subline C of Balb/3T3 cells was from Dr. Lloyd Culp (Case Western Reserve University, Cleveland, Ohio); subline M of Balb/3T3 cells was from Dr. Gerd Maul (Wistar Institute, Philadelphia, Pa.). Each subline was initially grown to a population of about 10^7 cells and frozen in equal parts of 20% glycerol-saline and medium. For routine use, an aliquot of 10^6 cells was thawed and recultured. Except for certain specific experiments, Balb/3T3 cells were split 1:20 to 1:100 once or twice weekly as needed to minimize cell-to-cell contact (as judged with an inverted microscope).

The nude BALB/c mouse fibroblasts were initiated as a cell strain in our laboratory. Embryos at day 16 of gestation, which were the product of a (*nu/nu*) × (*nu/nu*) homozygous mating, were removed aseptically, minced, and digested with 0.25% trypsin (Difco Laboratories, Detroit, Mich.) in Puck's saline A (*9*) for 45 minutes at 20°C in a stirring apparatus. The trypsinized preparation was spun at 500×*g* for 10 minutes, and the cells were resuspended in medium and distributed to three T150 flasks. As cultures reached confluence, they were split at a 1:2 ratio every 3–4 days into T75 flasks until culture crisis occurred at passage 8. From passages 8 through 12, growth slowed and 7–10 days were required to reach confluence. After crisis, split

ratios of 1:5 to 1:10 were used. Every fifth passage about 10^7 cells were frozen in 10% glycerol-medium, and preparations were made for chromosome studies. For experiments, samples of the various passages were used within two passages of thawing. SVT2 cells, a simian virus 40-transformed line of Balb/3T3, were obtained from Dr. Lloyd Culp. Human diploid fibroblasts (CRL 1295, passages 12–20) were provided by Dr. Gary Strniste (Los Alamos National Laboratory).

Culture conditions.—Monolayer cell cultures were grown in T75 or T150 flasks (Falcon Plastics, Los Angeles, Calif.) in Dulbecco's modified Eagle's minimum essential medium (GIBCO, Grand Island, N.Y.) with 10% FCS. However, human diploid fibroblasts recieved medium containing 20% serum. The cells were grown in 5% CO_2 at 37°C and passaged with 0.25% trypsin in Puck's saline A. For some experiments, cultures were maintained in medium with 0.1 mg TPA/ml obtained from Dr. Peter Borchert (University of Minnesota, Minneapolis, Minn.) and 0.005% acetone (Matheson, Coleman, & Bell, East Rutherford, N.J.); control cultures with 0.005% acetone were used.

For sponge cultures, 10^6–10^7 cells obtained from monolayer culture by trypsinization were resuspended in 5-ml sterile plastic tubes (Falcon Plastics). The tubes were kept in the same incubator as that used for monolayer culture. Gelfoam (The Upjohn Co., Kalamazoo, Mich.) sponges ($\approx$200 mm^3 in vol) were prepared from individually wrapped, presterilized, 20×60×7-mm slabs by means of a sterilized office paper punch. The sponges were hydrated in media and spun at 300 rpm for 20 minutes for removal of air. The number of cells per sponge was determined by incubation of individual sponges in 10 ml of the 0.25% trypsin solution containing 0.04 mg collagenase/ml (Worthington Biochemical Corp., Freehold, N.J.) for 10–15 minutes. Cells were then enumerated with a Coulter counter with the use of blank sponges as controls. For studies of cell growth fewer cells were seeded initially (10^5 for 20 sponges), and the media were changed twice weekly. Sample sponges were removed daily and counted. For routine sponge tumorigenicity tests, cultures were used within 1–3 days, at which time the samples were counted and fixed in 10% Formalin for histologic examination.

Tumorigenicity tests.—We performed sponge assays by decanting sponge cultures into 10-mm petri dishes (Falcon Plastics) and using forceps to implant individual sponges in the subcutaneous space (or other site) of mice; for some experiments, intraperitoneal implantation was done in the same manner; in either case, a 5-mm incision was made in mice that had been given intraperitoneal anesthesia with 60 mg pentobarbital/kg body weight. The incision was closed with a 9-mm Autoclip (Clay Adams, Inc., Parsippany, N.J.), which was removed 10 days later. Some implants were later removed from animals by similar surgical techniques. Such sampled implants were fixed in 10% buffered Formalin for histologic examination or minced and recultured in monolayer. Some implants were digested with stirring, with the use of the trypsin-collagenase mixture mentioned above, and the recovered cells were then processed for determination of DNA content (*see* below).

Suspension cell assays for tumorigenicity were done with the use of 10^6 trypsinized single cells suspended in 0.2 ml of media injected sc.

Transformation assays.—We determined saturation density by seeding 60-mm petri dishes with 5×10^4 cells; media were changed, and trypsinized cells were counted every other day for 10 days. Growth of cells suspended in Methocel was tested by the method of Risser and Pollack (*10*). Cells determined to be at least 99% free of microscopic cell clumps were suspended in Methocel at concentrations of 10^5, 10^4, 10^3, and 10^2 cells/plate with three replicates at each concentration. We determined that colonies with at least 25 cells could be directly visualized. Such colonies were scored and the number was confirmed with the use of an inverted microscope. Plating efficiency was calculated for plates with the appropriate cell concentration as the average number of colonies per plate divided by the number of cells plated. If no colonies formed with the highest number (10^5), then these plates were evaluated for more limited growth. We scanned at least 10^3 cells at random looking for microscopic colonies. Plating efficiencies of 0%, therefore, mean that fewer than 1 of 3×10^5 cells formed macrocolonies (>25 cells) and that no more than 1% of cells grew in a more limited fashion. SVT2 cells with a high colony-forming efficiency in Methocel were used as positive controls in all assays.

Chromosome studies.—Confluent monolayers of WNME were split every fifth passage to provide a 24-hour culture in exponential growth for chromosome preparation. They were blocked with Colcemid (0.06 μg/ml) for 2 hours, harvested by trypsinization, and pelleted by slow centrifugation. The pellet was resuspended in 1 ml medium that was made hypotonic by addition of 0.07 N KCl for 7 minutes. The cells were again gently pelleted and fixed by repeated dispersions (at least three times) in freshly prepared 3:1 methanol-acetic acid for 10-minute intervals. The final pellet was resuspended in fixative, spread on cold, wet slides, and air dried. The slides were stained with 10% Giemsa (G. P. Gurr, Ltd., London, England) at a pH of 6.8 for 10 minutes.

Photomicrographs were made of 30 metaphases on each slide, and the chromosomes per metaphase were counted.

DNA content determinations.—Single cell suspensions were spun at 1,500 rpm for 10 minutes, resuspended in 70% ethanol, and stored at 4°C for at least 24 hours. The cells were then removed from the ethanol and resuspended in mithramycin (Pfizer Inc., Groton, Conn.), 100 mg/ml in 0.15 M NaCl with 15 mM $MgCl_2$ at a final concentration of 10^5 cells/ml (*11*). DNA content distributions were determined with the use of the Los Alamos flow cytometer, which has been described in detail elsewhere (*12*).

Animals.—The nude mice in our colony originated from five breeding pairs (*nu/nu* males × *nu*/+ females) of BALB/c mice obtained from ARS/Sprague-Dawley Division, The Mongul Corporation, Madison, Wis., in January 1978. Since that time all experimental mice have been produced from similar life-mated pairs. For some studies homozygous (*nu/nu* × *nu/nu*) matings were employed. A single room was used for animal housing and all in vivo manipulations. The ventilation system was High-Efficiency Particle Arrestance filtered and provided a slight positive pressure in relationship to adjacent rooms. Entry was re-

[a] Calculation of mode and range was done only on animals with tumors. When no tumors were obtained, the period of observation is given preceded by >.

[b] In this experiment syngeneic, immunocompetent (*nu*/+) mice were used.

stricted to personnel directly associated with the experiments, and individuals were required to pass through an air lock-change room where they put on sterile gowns, shoe covers, masks, and gloves. Autoclaved cages, bedding, food, and water were changed twice weekly, and the mice were checked weekly for tumors. Routine serologic tests for a standard array of murine viruses have all been negative. Pathogenic bacteria have not been detected by frequent culture of utensils or excreta. Fewer than 20 nonexperimental deaths out of over 1,000 deaths have occurred since the colony started. For some studies, heterozygous (*nu*/+) mice produced in the colony were used as immunocompetent controls.

RESULTS

Tumorigenicity of Balb/3T3 Sublines

Of the three Balb/3T3 sublines studied, sublines A and C were tumorigenic in nude mice after a latent period of 3–4 months, but subline M did not produce tumors in several trials (table 1). When immunocompetent (*nu*/+) syngeneic mice were used as hosts, no tumor formation was demonstrated with subline A.

The differences in tumorigenicity between sublines A and M were not accompanied by differences in in vitro characteristics. Both sublines A and M failed to grow in Methocel, and both had low saturation densities in monolayer culture and on sponges (table 2). Cultures allowed to reach confluence did not show morphologic alterations in monolayer pattern.

TABLE 2.—*Saturation densities of cells in monolayer and sponge culture*

Cell type	Monolayer: Cells/$cm^2 \times 10^{-4}$	Sponge: Cells/sponge$\times 10^{-4}$

WNME, passage 65	13	17

Phases in Tumor Formation by Balb/3T3 Subline A

In the initial testing of subline A by the sponge method, three phases of tumor formation were noted.

Phase I (wk 1–8): The subline A implants were not grossly or histologically distinguishable from the subline M implants or from blank sponges (without cells) except that subline A implants persisted and enlarged slightly.

Phase II (wk 8–14): Nodules formed at each implant site. The nodules persisted at about 7 mm in mean diameter. By this time the implants of subline M and the blank sponges could not be detected either by external inspection or by dissection. During a similar time period, mice tested with suspensions of subline A cells (some of these mice would eventually develop tumors) showed no externally discernible lesions.

Phase III (later than 14 wk): Some of the nodules resorbed spontaneously, whereas others became rapidly progressive tumors at various times after 14 weeks. Also in the same time period, the mice tested with suspensions of subline A cells began to show rapidly progressive tumors without a preceding nodular phase. The fibrosarcomas produced by both assays were moderately well differentiated with occasional hypocellular, myxoid areas.

A more detailed study of subline A tumor formation was made with the use of 18 nude mice, 8 of which were implanted with two sponges each. One of the two sponges was removed from 1 or 2 of the mice at 2-week intervals and examined for histology or for DNA content (either in a direct manner or after reculture in monolayer). Table 3 shows that three phases occurred as before.

The histology of this series of implants is illustrated in figure 1. Vascularization and proliferation of subline A cells within the sponge were seen at 2 weeks. Between 4 and 8 weeks, the sponge was replaced by an encapsulated, myxoid proliferation of cells, including rare signet-ring cells resembling lipoblasts. Subline M implants also showed the myxoid proliferation during the period before their involution. These hypocellular nodules were similar to the myxoid areas in the tumors. Implants removed after 10 weeks tended to show hypercellularity in their capsules, a pattern consistent with that of a fibrosarcoma. Histologic sections of blank sponges removed at 2-week intervals during phase I showed minimal inflammatory response and progressive organization by granulation tissue (fig. 2). The granulation tissue included ingrowing blood vessels and collagen deposition.

TABLE 3.—*Fate of Balb/3T3 sponge implants by time*

Phases	Subline[a]		Blank sponge[a,b]
	A	M[b]	
Phase I: Nodules before 8 wk	16/18	19/19	13/13
Phase II: Nodules at wk 8–14	16/18	0/19	0/13
Phase III:			
Progressive tumors after 14 wk	11/18	0/19	0/13
Spontaneous resolution after 14 wk	4/18	19/19	13/13
Persistent nodule after 14 wk	3/18	0/19	0/13

[a] Results are expressed as No. of animals with nodules/total No. of animals examined.

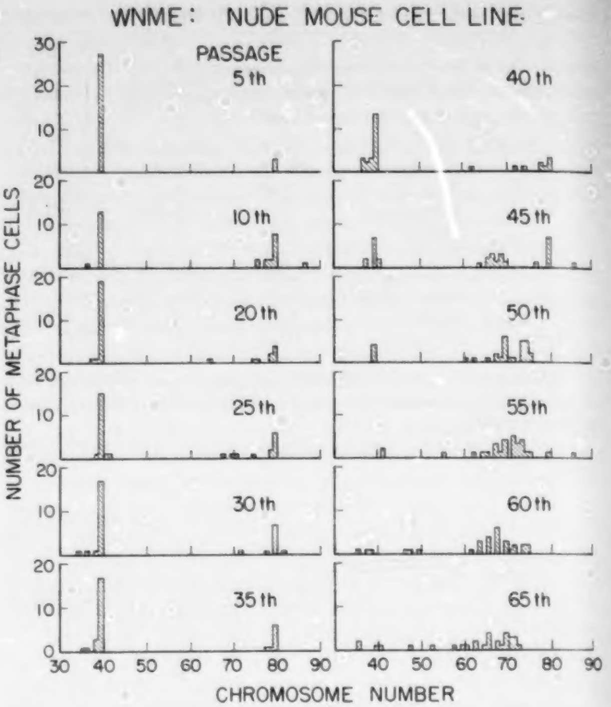
[b] The results obtained with subline M and blank sponge are taken from table 1 for comparison with the results of the subline A study.

TABLE 4.—*DNA content of cells recovered from strain A implants versus parent strain in culture*

Time after implant	Recovery method	G_1 DNA content[a]
6 wk	Explant culture	1.79
8 wk	Nodule digestion	1.33
10 wk	Explant culture	1.96
10 wk	Explant culture	1.92
Parent strain	Routine culture	1.61

[a] This content is the DNA content of cells which are in the G_1 portion of the cycle relative to that of normal diploid controls. It is measured as the ratio of G_1 fluorescent intensity (modal channel number of the G_1 peak) of mithramycin-stained test cells over that of diploid control cells. The G_1-to-G_2 modal channel ratio was 2.08:2.17 for all diploid controls. Sample peaks showed coefficients of variation ≤4% and represented at least 10^4 cells.

Analysis of the DNA content of cells recovered from the subline A implants showed amounts distinct from those of the parent subline in cell culture (table 4). Of the four samples from the implants, the one obtained directly by digestion of the nodule and recovery of the cells was different from the other three as well as from the parent subline. This result indicated in vivo cell selection during phase I of tumor formation (as well as possibly during reculture of the implant). A minor peak of diploid cells of host stromal origin was also present in each suspension. Such peaks provided internal control for the G_1 phase ratio determinations.



TEXT-FIGURE 1.—Histogram of the number of chromosomes per cell in various passages of WNME. Thirty metaphases were counted for each passage.

Tumorigenicity of WNME

WNME at passage 35 formed tumors in the sponge assay as early as 3 months after implantation, but with the suspension test only one of the mice developed a tumor at 7 months (table 5). Earlier passages tested were nontumorigenic, whereas later ones were rapidly tumorigenic by both methods. Exposure of cells to TPA for 2 or 3 weeks before implantation did not materially change the results. Samples for histologic study of sponge implants from passages 35 and 50 were taken at 8 weeks. The passage 35 implants (barely large enough to sample at this time) showed foci of spindle cells within and surrounding the remnants of sponge matrix. The passage 50 implants were much more cellular and sufficiently atypical to be called sarcomatous. Implants of earlier passages (5 and 20) were too small to be visualized reliably by 8 weeks.

TABLE 5.—*Tumorigenicity of WNME at various passages*

Passage No.	Assay	No. of tumors/No. of mice	Inoculum, $\times 10^{-4}$ cells	Latent period,[a] mode/range in mo
5	Sponge	0/17	6–28	>9
20	Sponge	0/18	16–32	>9
	Suspension	0/9	160–320	>9
	Sponge TPA	0/7	52	>9
35	Sponge	3/9	15	3, 5
	Suspension	1/7	310	7
	Sponge TPA	7/8	62	4/3–5
50	Sponge	14/16	10–58	3/2–4
	Suspension	5/8	230	5/3–7

[a] Cells were plated at 0.05×10^5 cells/cm^2 with and without 0.1 mg/ml TPA. ND = not done.

[b] Zero means <1 colony in 10^5 cells. The TPA concentration was 0.1 g/ml.

[c] This value was calculated from cultures in T150 flasks with twice weekly refeeding for 1-2 wk.

[d] The cells formed tumors in the sponge assay only (as per table 5).

[e] The cells formed tumors in both assays (as per table 5).

crisis passages before and after passage 35 showed that the only obvious change was in karyotype. Fully tumorigenic passage 50 cells were blatantly heteroploid, but both passages 20 and 35 showed minor aneuploid subpopulations as did all crisis and post-crisis passages (text-fig. 1).

Saturation density did not change significantly and had not changed from the value calculated for primary cultures of WNME; growth in Methocel was not demonstrable (table 6).

These passage levels were also tested for in vitro response to TPA. TPA increased saturation density in all passages and allowed a very low frequency of growth in Methocel at passage 50 (table 6). Likewise, it produced morphological changes in all cases (fig. 3).

DISCUSSION

Collagenous sponges have been shown to be suitable growth substrates for a wide variety of cells (*13–16*). The use of collagenous sponges for studies of tumorigenicity was also encouraged by the ability of collagen to stimulate angiogenesis in vivo (*19*). Sponges implanted sc in nude mice are externally visible and can be recovered from the animals and the cells can then be recultured. The specific use of the system reportd here was to investigate the expression of the spontaneously acquired tumorigenicity that is characteristic of rodent cells when they are carried in routine culture for extended periods. In particular, we wished to examine further the possibility suggested by the studies of Boone and co-workers (*17,18*) that such culture conditions (which imply attachment to glass or plastic) followed by implantation while still attached to plastic plates combine to initiate and/or promote spontaneous malignant change. In the studies of Boone et al., this kind of effect was seen for both untransformed, permanent cell lines and for early-passage adult mouse connective tissue cells. One question that we asked was whether the highly fenestrated surface of our gelatin sponges could replace the plastic plates in the second stage of Boone's system. This question was asked both for sublines of the untransformed Balb/3T3 cell line and for WNME at varying levels of passage.

For the Balb/3T3 sublines the answer was that anchorage to fenestrated gelatin did not replace the effect of plastic plates. Balb/3T3 subline M was not tumorigenic on gelatin. Nor did variations in the site of inoculation (ip), with the use of Sephadex beads (Superbeads TM, Microcarriers; Flow Laboratories) as the substrate, or coinjection with 10^7 human diploid fibroblasts [by the method of Sager and Kovac (*20*)] suffice to allow subline M to form tumors (Kraemer PM, Wells RS: Unpublished data). Balb/3T3 subline A did not require the gelatin substrate to form tumors, but it did require the environment of the nude mouse since it was not tumorigenic in immunocompetent (nu^+) syngeneic hosts (comparable to the normal BALB/c hosts used by Boone). Further, the slow tumor formation of subline A in nude mice did not appear to be simple selection of a single preexisting variant or subclone. First, the subline A sponge tumors went through a distinctive myxoid nodule stage before either forming progressive tumor or resolving. Second, 4 of 4 such nodules whose cells were analyzed for DNA content had unique values (i.e., were from separate stem lines or clones).

One possible explanation for these data is that the Balb/3T3 sublines are initiated cells that require further promotion. Such promotion might be provided by plastic plates (in the case of subline M) via a mechanism analogous to in vivo solid-surface sarcomagenesis as proposed by Boone et al. (*18*). In contrast, the highly fenestrated gelatin surface does not meet the geometric requirement in order to promote foreign-body sarcomas (*21*). Also, subline A cells might be beyond the need for this promotion step but still not fully tumorigenic in immunocompetent, syngeneic hosts.

An alternative explanation is that some untransformed cell lines do not form tumors in immunocompetent hosts because they have neoantigens. In that case the plastic plates might exert their effect by an immunosuppressive effect; this effect could be generalized or localized, such as the effect suggested for UV light-induced skin carcinogenesis in which altered antigen processing in the skin has been incriminated (*22*). It would be interesting to know if Boone's Balb/3T3 and C3H/10T½ cells are tumorigenic in nude mice.

For the WNME our data show that anchorage to gelatin sponges enhanced the expression of tumorigenicity of early post-crisis cell populations. These results are consistent with the data of Boone et al. (*18*) for adult mouse connective tissue cells, in that carrying cells on plastic surfaces yielded premalignant, but anchorage-dependent lineages. However, our results and the results of Boone et al. differ markedly. The effect of Boone et al. was demonstrable for cells after 1 passage in culture, while our effect required over 20 passages. This inconsistency may reflect any one of several differences between adult connective tissue lineages and cultures initiated with whole mouse fetuses. More definitive experiments are now in progress, i.e., studies of lineages initiated and cultured exclusively on gelatin sponges.

The results with both study systems confirm those of other reports (*2, 6, 23–25*) which indicate weaknesses in the predictive usefulness of in vitro parameters of cancer. In the case of our study of permanent cell line evolution, these parameters did not herald the onset of tumorigenicity, and even passage levels that were frankly heteroploid and tumorigenic by conventional assay were not transformed according to these in vitro parameters.

Similarly, the differences between Balb/3T3 sublines were not paralleled by differences in in vitro behavior. Nor did vascularization or initial cell proliferation on the sponges in vivo predict tumor formation. One advantage of the sponge assay is that such in vivo factors can be evaluated up to 2 months after the cells are implanted. The rapidly tumorigenic, 50th and 60th passage nude mouse embryo cells that evolved in culture were not transformed as defined by our in vitro assays (except for being frankly heteroploid as were the other untransformed permanent cell lines). In particular, they were not anchorage-independent (anchorage-independent cells were not detected in samples many times as large as a tumorigenic dose), indicating that anchorage independence is not the only mechanism by which WNME became independent of the sponges for progressive tumor formation.

In this study "promotability" with TPA was not found, and in vitro responses to TPA did not prove to be markers of tumorigenic potential. Since all sponge implants were vascularized, this also does not appear to be the limiting step for expression of the tumorigenic phenotype as suggested by Folkman (*26*). Indeed, angiogenesis may be a very early attribute of initiated cells as suggested by Brem et al. (*27*). In summary, the spontaneous acquisition of tumorigenicity during serial cultivation of mouse cells was not predicted by commonly used in vitro indicators. This conclusion is also suggested in the work of Reid et al. (*28*).

Chromosome Changes Associated With the Progression of Cell Lines From Preneoplastic to Tumorigenic Phenotype During Transformation of Mouse Salivary Gland Epithelium In Vitro[1]

John K. Cowell[2,3] *and* **Caroline B. Wigley**[2,4,5]

ABSTRACT—Two mouse salivary gland epithelial cell lines, CSG 211 and CSG 205/2B1, isolated during carcinogen-induced neoplastic transformation in vitro, were analyzed cytogenetically before and after they acquired the ability to produce carcinomas in syngeneic animals. With the use of Giemsa banding techniques, chromosome changes were identified that were associated with the transition from a preneoplastic to a fully transformed (tumorigenic) phenotype during serial passage in vitro. Results were compared with those from a third cell line of similar origin, CSG 225, which was tumorigenic at the earliest passage tested. These cell lines were found to be subtetraploid, which confirms previous data, and the tumorigenic lines showed consistent losses of copies of chromosomes 1, 4, 7, 9, and 14. Compared with their preneoplastic counterparts, the loss of no single chromosome seems to be sufficient to generate the tumorigenic phenotype, but the loss of a combination of some or all of these chromosomes appears to be important in the phenotypic transition. In CSG 211 the loss of chromosome 7 is probably more important in this respect than loss of the other chromosomes listed. The karyotype of this cell line undergoes major structural rearrangement, which suggests that loss of specific regions of chromosomes 1 and 9 is also important.—JNCI 1982; 69:425–433.

The majority of tumor cells from humans and experimental animals show substantial numerical and structural chromosome aberrations (*1*, *2*), but it is not always possible to determine whether the observed changes are related causally to the expression of the malignant phenotype or are a later consequence. In a few cases where analysis has been possible, chromosome aberrations have been shown to be associated with the progression from premalignant (preinvasive) to malignant (invasive) cells (*3–5*). The progression of myelocytic leukemia, often considered a preleukemia stage (*2*), to the acute blast crisis of the disease is frequently associated with the appearance of new chromosome aberrations (*2*, *6*).

Most human cancers are epithelial in origin, but the study of these cells in vivo is complicated by many factors (*7*). As yet, there is no in vitro transformation system for human epithelium, but recently it became possible to follow closely the development of neoplasia in vitro in epithelial tissue from experimental animals (*8*). In one particular system, chemically induced transformation in vitro of mouse salivary gland epithelium can be followed through a series of defined stages, resulting in the eventual production of fully transformed epithelial cell lines (*9–11*).

During in vitro transformation of mouse salivary gland epithelium, an increase occurred in the proportion of tetraploid cells in the preneoplastic foci (*12*). Accurate quantitation [*see* (*13*)] showed that in the later stages of transformation the DNA content of individual cells decreased, suggesting that chromosomes were being eliminated from these tetraploid cells, a process which eventually gives rise to subtetraploid cell lines (*12*). In the same study evidence was presented which suggested that similar events involving the same cell type occur during in vivo carcinogenesis.

A detailed analysis of eight well-established, tumor-producing cell lines showed that a nonrandom loss of certain chromosomes occurred (*14*). Although chromosomes 1, 4, 7, 9, and 14 were invariably lost, the time of their loss, whether before or after onset of tumorigenicity, could not be determined. In this study we have attempted to identify those chromosomes whose loss is specifically associated with the acquisition of tumorigenicity by preneoplastic cell lines. We hope to dissociate such specific changes from changes that occur randomly without selective advantage or that are involved in adaptation to growth in tissue culture.

MATERIALS AND METHODS

Cell lines.—Three cell lines, CSG 205/2B1, CSG 211, and CSG 225, were derived from mouse submandibular salivary gland ductal epithelium (*11*) transformed in vitro with the use of the hydrocarbon carcinogen BP. Foci of altered preneoplastic cells were isolated from BP-treated primary cultures. Most of the resulting cell lines could be subcultured for many passages before becoming tumorigenic in syngeneic animals. For a fuller account of the derivation and characterization of preneoplastic and fully transformed (tumorigenic) salivary epithelial cell lines, *see* (*10*).

The epithelial tumor cell line CMT 148 was derived from explant cultures of a tumor from CSG 205/2B1 cells.

All cell lines were maintained in Dulbecco's modified Eagle's minimum essential medium supplemented with 10%

ABBREVIATION USED: BP=benzo[*a*]pyrene.

newborn calf serum and 1% kanamycin sulfate. Cells were harvested with the use of EDTA-pronase (*10*) and were passaged with a 1:10 split ratio.

Chromosome analysis.—Chromosome preparations and subsequent trypsin-Giemsa banding analyses were usually performed as described previously (*15*). However, the presence of keratinizing cells in CSG 211, which seemed to prevent penetration of vinblastine and inhibited chromosome spreading, necessitated that the procedure be modified slightly for this cell line. The cells were harvested and treated with vinblastine in suspension; this procedure was followed by longer than usual hypotonic treatment (at least 20 min).

For each cell line, 20 well-banded metaphases were analyzed. From these analyses, modal karyotypes were constructed representing consistent features of the cell line. [For further discussion, *see* (*14*)]. All karyotypes were based on the previously presented normal karyotype (*15*) from mouse embryo fibroblasts. The nomenclature used throughout is that of Nesbitt and Francke (*16*).

Tumorigenicity assays.—Cell lines, at the earliest possible passage after their isolation, were tested for tumorigenicity by sc injections of 2-5×10^6 cells into syngeneic hosts. Subsequently, the cell lines were tested at appropriate regular intervals. These numbers of cells were chosen for routine testing of tumorigenicity after it had been shown that the most malignant salivary epithelial cell lines available in our laboratory [e.g., CSG 120/7 (*9*)] failed to produce tumors consistently from inocula of less than 10^6 cells and that there was no advantage with respect to tumor incidence or growth rate in injecting more than 5×10^6 cells (Wigley CB: Unpublished data).

RESULTS

Three cell lines were isolated from preneoplastic foci before the occurrence of change in growth pattern and before evidence of morphology characteristic of tumorigenic cells (*10*). Two cell lines, CSG 211 and CSG 205/2B1, were nontumorigenic at early passages and, therefore, have a preneoplastic stage (table 1), but CSG 225 was tumorigenic from the outset. Both of the preneoplastic cell lines eventually gave rise to tumorigenic cell lines after varying lengths of time in culture. In an attempt to detect specific chromosome changes associated with the onset of tumorigenicity, we undertook a detailed G-band chromosome analysis of the preneoplastic and tumorigenic cell lines.

CSG 211 Cells

Preneoplastic.—A representative karyotype with modal number 67 from passage 11 is shown in figure 1. The main feature of this karyotype is the absence of copies of individual chromosomes that presumably were lost from progenitor tetraploid cells (*12*). Details of these losses are summarized in table 2. There was only one structural chromosome rearrangement which involved the translocation of a small chromosome region onto the distal end of 4q (fig. 1), with the breakpoint in band 4C3. The difficulty in identifying the origin of the translocated region was due to the fact that the translocation is not a reciprocal one; i.e., no other chromosome in the karyotype shows a deletion. We must assume, therefore, that after the rearrangement event the chromosome from which the translocated segment arose was lost. If this is the case, then the most likely source of the extra chromosome material is chromosome 13.

TABLE 1.—*Summary of cell line tumorigenicity as related to passage level of inoculated cells*

Cell line	Passage level	No. of tumors/No. of mice
CSG 211	5-18	0/11
	23-37	7/7
CSG 205/2B1	6-12	0/5
	14	2/4
	16-26	11/13

TABLE 2.—*Chromosome losses in preneoplastic and tumorigenic salivary gland epithelial cell lines*

Cell line (passage level)	Modal chromosome No.	Chromosome losses[a]	Rearrangements
CSG 211			
Preneoplastic (11)	67	1, 2, 3, 4, 9, 13, 14, 15, 16, 17 (2), 18, Y	T(?;4)
Tumorigenic (33)	59	1 (2), 2, 3, 4 (2), 7, 8, 9 (2), 10, 11, 12 (2), 13, 14 (3), 15 (2), 16 (2), 17 (2), Y (2)	T(1;5), T(9;10), T(14;?), T(4;?), M5
CSG 205/2B1			
Preneoplastic (13)	71	1, 2, 4, 7, 8, 9 (2), 12 (2), 13, 14 (2), 15 (2), 17	T(8;12), T(6;?), M3, M4, M5, del 4
Tumorigenic (26)	69	1, 2 (2), 3, 4, 6, 7, 8, 9, 12, 14 (2), 15, 17, Y	T(8;12), T(6;?), M3, del 4, del 14
CMT 148[b]	71	1, 2, 3, 4, 6, 7, 8, 9, 12 (2), 14, 17, Y	T(8;12), M2, M3, del 4, del 6, del 14

[a] One chromosome copy from each group was missing from a tetraploid cell unless otherwise specified *in parentheses*.

[b] Derived from explant cultures of CSG 205/2B1 cells at passage 16.

Tumorigenic.—The mean chromosome number of passage 33 cells is 59, eight fewer than that of the preneoplastic cells. The karyotype of the tumorigenic cells is shown in figure 2. During evolution of this cell line, several structural rearrangements have arisen (fig. 3). A description and tentative identification of these rearrangements follows: M1—T(1;15)(1D;15D2); M2—T(9;10)(9D;10D2); M3—deletion of the distal region of the marker chromosome in CSG 211/11 (fig. 1), which was replaced by a small unidentified chromosome region, with the breakpoint in band 4C3; M4—translocation of chromosome 14, possibly with a centromeric breakpoint to the proximal region of an unidentified chromosome; and M5—rearrangement could not be identified.

Changes in karyotype—A study of the modal chromosome numbers alone shows that there was a loss of eight chromosomes during the transition from preneoplastic to tumorigenic cell line. However, as shown in table 3, when the chromosome markers were analyzed in more detail, only copies of chromosomes 7, 11, 12, 14, and 16, in addition to the Y-chromosome, were completely missing, and there was a gain of one copy of chromosome 18. Often regions of other chromosomes were lost as a result of chromosome rearrangement (table 3). In CSG 211/11 the marker chromosome, tentatively identified as the translocation of 13D→ter to 4C3, was no longer present in the same form but appeared to have undergone further rearrangement.

CSG 205/2B1 Cells

Preneoplastic.—Up to passage 12, no cell implant had produced tumors within the 18-month observation period (table 1). Passage 14 cells showed a 50% tumor incidence after a long latency period, suggesting that selection of variant tumorigenic cells from a heterogeneous population had taken place in vivo. The earliest passage level at which good G-banded preparations were obtained was passage 13 where the majority of cells could be considered to be non-tumorigenic (preneoplastic). The karyotype of passage 13 cells is shown in figure 4 and has a modal number of 71. Losses of individual chromosomes are summarized in table 2. At least five and sometimes six copies of chromosome 5 were present in all cells at this passage. Unlike the preneoplastic CSG 211 cells, several structural rearrangements occurred in the early passage of CSG 205/2B1 cells. These are shown in figure 3. A consistent feature of the cell line was the terminal deletion of chromosome 4, with the breakpoint at band 4C7. Other consistent chromosome changes were: M1—a complex translocation apparently involving deletion of chromosome 8 distal to band 8D1, with the possible duplication of band 8D1 and the translocation of most of chromosome 12 distal to band 12B onto the duplicated region; and M2—translocation of a large chromosome region to the distal tip of chromosome 6, with the breakpoint in 6F1. This translocated region does not resemble that of any other chromosome, and possibly the relocated region originated from several chromosomes.

Chromosome markers M3, M4, and M5 were small chromosomes that arose from the proximal region of unidentified chromosomes. Similar fragments were also characteristic of many other salivary gland cell lines (*14*), but relevance to the phenotype of these cells was difficult to assess because of their variable presence in individual cells of any particular cell line.

At passage level 13, two Y-chromosomes were present in the majority of cells.

Tumorigenic.—Passage 24 cells produced carcinomas after 4–6 weeks (table 1), as compared to longer times at earlier passage levels. Karyotype analysis at passage 26 was chosen as representative of the fully tumorigenic cell line (fig. 5). The modal chromosome number is 69. A detailed chromosome analysis revealed that major karyotypic reorganization occurred, the details of which are summarized in table 2. Five copies of chromosome 5, the terminal deletion of chromosome 4, and the two large marker chromosomes M1 and M2 were also retained in the tumorigenic cells. Two of the small chromosome markers were lost in the tumorigenic cell line. The only new structural aberration in the fully transformed cells involved the terminal deletion of chromosome 14 distal to band 14E2.

TABLE 3.—*Chromosome changes associated with progression of CSG 211 and CSG 205/2B1 from preneoplastic to tumorigenic cell lines*

Cell line	Whole chromosome changes[a]	Deleted chromosome regions[b]
CSG 211	−7, −8, −11, −12 (2), −14, −16, +18, −Y, +M5	1 cen→1D 15D2→ter, 10D2→ter, 9cen→9D
CSG 205/2B1	−2, −3, −6, +9, +12, +13, +15, −Y, −M3, −M5	14F2→ter

[a] One chromosome copy from each group was missing from a tetraploid cell unless otherwise specified *in parentheses.*

[b] Breakpoint terminology is according to Nesbitt and Francke (*16*).

Although the Y-chromosome is included in the karyotype in figure 5, it was missing in half of the cells analyzed.

Changes in karyotype.—The reduction in chromosome number by two during the transition of the CSG 205/2B1 cells from a preneoplastic to a tumorigenic cell line could theoretically be accounted for by the loss of the two small chromosome markers. Closer analysis revealed that this explanation was too simple, inasmuch as considerable chromosome reorganization had occurred (table 3). This finding emphasizes the caution that must be exercised when one draws conclusions from chromosome counts alone.

Terminal deletion of chromosome 14 represents the only new chromosome aberration associated with the tumorigenic cells, but losses of chromosomes 2, 3, and 6 and the Y-chromosome also occurred. The tumorigenic cells gained copies of chromosomes 9, 12, and 13, when compared with the preneoplastic cells, presumably as a result of nondisjunction. Cowell in (*14*) suggested that in the transformed cell lines certain chromosomes carry mutations, which if in excess may be responsible for the expression of the malignant phenotype. These imbalances may be achieved by the loss of one or both of the "normal" homologues. So far, losses of chromosome 9 have been found in all of the transformed salivary gland cell lines, often with two copies lost. If CSG 205/2B1 cells at passage 13 have already lost the two normal homologues, then nondisjunction of one of the "mutant" chromosomes, while increasing the number of copies, still represents a chromosome imbalance.

At regular intervals during in vitro passage of both CSG 205/2B1 and CSG 211, cells were tested for tumorigenicity (table 1). Although cell implants from CSG 211 proved negative for many passages, the findings for CSG 205/2B1 were not so clearly definable. Cell implants from about passage 16 of CSG 205/2B1 produced tumors but only after many months in vivo, and the latent period was much longer than that for cells of later passages. We attempted, therefore, to determine whether the cells in such tumors were derived as a result of the selection in vivo of a minority population of cells preexisting in vitro or whether the population arose de novo after inoculation in vivo. One of these tumors was cultured, and cell line CMT 148 was established to distinguish between the two possibilities.

CMT 148 Cells

The karyotype of cells from passage 8 of CMT 148 is given in figure 6. The cells have a modal chromosome number of 71. Losses of individual chromosomes are given in table 2, and a comparison of the karyotype of the CMT 148 cell line (derived from passage 16 of CSG 205/2B1 cells) with the karyotypes of preneoplastic and tumorigenic CSG 205/2B1 cells is summarized in table 4.

Certain chromosome abnormalities common to both the preneoplastic and tumorigenic cell lines, such as the terminal deletion of chromosome 4 and the excess of chromosome 5, are also present in CMT 148. With the exception of the variable presence of the small marker fragments, the CMT 148 tumor cell line only resembled the preneoplastic cell line in two respects (table 4), and the overall karyotype resembled the tumorigenic cell line at passage 26. The only new structural aberration was the deletion of the terminal region of chromosome 6 distal to band 6E. Chromosome gains had occurred in normal copies of chromosomes 14 and 15. CMT 148 now has four copies of chromosome 15, presumably as a result of nondisjunction.

CSG 225 Cells

This cell line was isolated from primary culture in the same way as were lines CSG 211 and CSG 205/2B1, but even at passage 9 it consistently produced invasive carcinomas (*10*). Clones from an early passage of CSG 225 cells were also tumorigenic (Wigley CB: Unpublished data) and had, therefore, no detectable preneoplastic stage. A description of this cell line was included for comparison with lines CSG 211 and CSG 205/2B1. Detailed chromosome analysis of cells from passage 9 showed that the majority were in the suboctaploid range, with only a minor subpopulation of cells in the subtetraploid range. Therefore, these higher ploidy cells apparently have a selective advantage in culture and presumably arose as a result of endoreduplication of the subtetraploid cells. A similar situation was described in another salivary gland cell line, CAE 553 (*14*). A modal karyotype could not be constructed from the very limited number of subtetraploid cells available, but a sample karyotype of a single CSG 225 cell (fig. 7) shows that there were many chromosome losses. The average chromosome number was in the range 62–65, and chromosomes 1, 4, 7, 9, and 14 and the Y-chromosome were missing. These losses were consistent with findings for the tumorigenic cell lines described in this paper and previously (*14*). Another consistent feature was the excess of chromosome 5; chromosome 19 was also in excess.

DISCUSSION

The loss of certain chromosomes from tetraploid cells has been implicated in the transformation of mouse salivary gland epithelium (*14*). All three tumorigenic cell lines described in this paper were also subtetraploid and, within a background of random loss, chromosomes 1, 4, 7, 9, and 14 were missing consistently, confirming previous results (*14*). In the experiments reported in this paper it was possible to analyze the chromosomes of preneoplastic cells, follow them through the transformation process, and compare their karyotypes with those of the tumorigenic derivatives. No single chromosome change apparently was associated with this transition. In cell line CSG 211, complete copies of chromosomes 7 and 14 were lost during the transition from a preneoplastic to a tumorigenic phenotype, with most of one copy each of chromosomes 1 and 9 also lost. Thus of the nonrandom changes noted previously in the fully transformed cell lines, apparently only chromosome 4 was not involved (*see* later). In CSG 205 cells a small region of chromosome 14 was lost during the transition—the only change common to both cell lines. In line CSG 225, no preneoplastic phase could be identified, but chromosomes 1, 4, 7, 9, and 14 were also underrepresented in the tumorigenic cells.

TABLE 4.—*Comparison of CMT 148 karyotype with karyotypes of preneoplastic and tumorigenic CSG 205/2B1 cell lines*

CSG 205/2B1 cell lines	CMT 148 chromosome aberrations	
	In common with CSG 205/2B1[a]	Different from CSG 205/2B1
Preneoplastic (P)	−2, −12 (2), M3, M5	—
Tumorigenic (T)	−3, −6, −9, +13, −Y, del 14	—
Both P and T	−1, −4, +5, −7, −8, −17, del 4, M1	del 6, +14, +15

[a] One chromosome copy from each group was missing from a tetraploid cell unless otherwise specified *in parentheses*.

The two cell lines CSG 211 and CSG 205/2B1 behaved differently during their progression from preneoplastic to tumorigenic cell lines. The differences in behavior also were reflected in their karyotypic changes. CSG 211 was in continuous culture for more than 5 months, from the initial karyotyping at passage 11 to passage 23 when the cells were consistently tumorigenic. During this time the cells were tested at regular intervals, and within the 18-month period of animal observation no tumor arose from CSG 211 cells before passage 23, four passages earlier than stated in the preliminary data presented previously (*10*). During this time in vitro, the cells had undergone major karyotypic changes. In comparison, cell line CSG 205/2B1 was first karyotyped at passage 13 and was initially considered to be tumorigenic at passage 22 (*10*). Since these observations, a proportion of tumorigenicity tests have proved positive at earlier passages but only after a long latent period in vivo. This finding indicates that whereas CSG 211 may have undergone the relevant structural chromosome reorganization fairly late in its culture history, the tumorigenic subpopulation of CSG 205/2B1 appears to have evolved relatively early, although selection for this subpopulation in vitro occurred gradually over a longer period. Analysis of CMT 148, the cell line derived from the tumor that arose from passage 16 of CSG 205/2B1 cells, reveals karyotypic features of both the preneoplastic and tumorigenic cell lines, but features of the tumorigenic line predominate. This observation suggests that these cells were selected in vivo, just as they were selected in vitro, from a heterogeneous parent population. Of possible relevance is the deletion of part of chromosome 14. The importance of the loss of this chromosome has been implicated in all other cell lines. [*See* above and (*14*).]

CSG 211 perhaps offers better insight into the changes involved in the transition of preneoplastic cells to tumorigenic cells, inasmuch as the transition seems to be relatively abrupt in this cell line. Perhaps of most interest is the finding that chromosomes 1, 7, 9, and 14 are involved, particularly chromosome 7. The preneoplastic cells have four copies of chromosome 7, whereas one copy of chromosome 7 is missing in the tumorigenic cells. An additional chromosome 14 is lost, leaving only two, a common feature of the other tumorigenic cell lines (*14*), particularly those transformed in vivo. The other chromosomes, 9 and 1, were involved in rearrangements resulting in the loss of parts of these chromosomes. That these karyotype changes are simply an adaptation to in vitro growth is unlikely inasmuch as CSG 211 cells had grown rapidly from the first passage, with no marked increase in growth rate associated with the acquisition of tumorigenicity.

Unlike any of the tumorigenic cell lines reported in this paper or previously (*14*), CSG 211 cells at passage 33 contained many structural chromosome rearrangements in addition to the small marker chromosomes so often seen. Possibly simple loss of whole chromosomes in this cell line is insufficient to generate the malignant phenotype. Analysis of the markers has shown that as a result of nonreciprocal chromosome rearrangements, certain parts of chromosomes were lost, notably from chromosomes 1 and 9. These observations may indicate that these regions carry important information that controls expression of the malignant phenotype. Why should rearrangement, rather than whole chromosome losses, occur in this cell line? One possibility is that these cell lines carry recessive mutations so that loss of the whole homologous chromosome would be lethal. However, loss of certain regions may be required to create a genetic imbalance and allow expression of the malignant phenotype (*17*). As a result of rearrangement, these regions could be lost or their expression suppressed while the lethal mutations remain balanced. This may also account for the long preneoplastic period inasmuch as appearance of these rearrangements is likely to be a rare event. From the analysis of the two cell lines, particularly of CSG 211, a combination of chromosomes or chromosome regions apparently must be lost to allow expression of the malignant phenotype.

In both CSG 211 and CSG 205/2B1, chromosome 4 was shown to be structurally abnormal. In CSG 205/2B1 a terminal deletion of chromosome 4 occurred, and in CSG 211 two rearrangements resulted that involved the same terminal region although the nature of the rearrangement changed during the transition from preneoplastic to tumorigenic cells. In addition to the structural rearrangement, one copy of chromosome 4 was missing, which was also one of the consistent features of tumorigenic salivary gland cell lines (*14*). In these cell lines the same terminal region of chromosome 4 was also involved in structural rearrangements, suggesting that the region was a nonrandom site for chromosome rearrangement. These findings are not restricted to salivary gland cell lines, and the terminal region of chromosome 4 also was reported to be involved in structural rearrangements in mouse bladder epithelial cell lines (*15*). The invariable loss of at least one copy of chromosome 4 in salivary gland cell lines might suggest some correlation with the expression of tumorigenicity in these cells, but the correlation could not be demonstrated conclusively in these studies. Whether structural rearrangement of the terminal region of chromosome 4 is important in the expression of the malignant phenotype is also uncertain. Somatic cell hybridization studies strongly implicated chromosome 4 in the expression of the malignant phenotype in the mouse (*18*). Recently, Lin and Ruddle (*19*) demonstrated that murine chromosome 4 is the probable site of a gene (or genes) for DNA repair synthesis that has been implicated in the development of cancer (*20*). Whether the enzymes involved in DNA repair are located in the terminal region of chromosome 4 is not known.

Effect of Type C Viral Expression and Cellular Karyotype on Human B-Lymphoblast Tumorigenicity in Nude Mice[1,2]

Anton F. Steuer,[3] Robert C. Ting,[3] Phillip D. Markham,[4] Zaki Salahuddin,[4] *and* Robert C. Gallo[5]

ABSTRACT—Cultured human hematopoietic cells from several normal and leukemic sources, including those cells initiated after exposure to primate type C retroviruses were tested for their capacity to induce tumors in young athymic BALB/c (*nu/nu*) mice after sc inoculation. An attempt was made to correlate these results with virus expression and chromosome patterns. Progressively growing tumor formation was observed in 5 of 18 normal diploid B-lymphoblast lines from normal peripheral blood and in one of three diploid B-lymphoblast lines from leukemic donors established after infection with primate type C viruses (gibbon ape leukemia virus or simian sarcoma virus). In contrast, none of eight spontaneously transformed B-lymphoblast lines with normal diploid karyotypes formed progressively growing tumors, although one formed a tumor that remained the same size (0.5 cm) for several months. Progressive tumor formation occurred in four of seven previously established cell lines of different cell types that had abnormal karyotypes. Of the normal diploid B-lymphoblast cultures exposed to type C viruses, 12 were tested for the presence of viral RNA and structural proteins (p12, p30, gp70), and this information was correlated with tumorigenicity. Four of the six cultures expressing viral RNA or proteins were tumorigenic, whereas only one of six cultures that did not express virus information was positive. The results of this study suggest that expression of type C viral RNA and proteins by human B-lymphoblasts increases their tumorigenicity in nude mice. It is also apparent that caution must be used in attempts to correlate cell tumorigenicity and chromosome abnormalities in nude mice.—JNCI 1982; 69:435–441.

The athymic nude mouse has been used for the assessment of tumorigenicity by cell lines from a number of species (*1*–*4*). Nilsson et al. (*5*) have reported that EBV-carrying human lymphoblastoid cell lines with a normal diploid karyotype did not form tumors when inoculated sc into nude mice. In contrast, the majority of lymphoblastoid cell lines with an aneuploid karyotype gave rise to malignant tumors. A recent study by Giovanella et al. (*6*) indicated that EBV-carrying human lymphoblastoid cell lines that exhibited a normal diploid karyotype could form tumors in nude mice under immunologically privileged conditions, such as after intracerebral inoculation.

We report here on 36 human hematopoietic cell lines, many of them recently established, which underwent karyologic analysis and were tested for their ability to produce subcutaneous growths in young adult nude mice. Some (6/20) human lymphoblast lines initiated with certain primate type C viruses produced subcutaneous tumors in nude mice despite their maintenance of a normal diploid karyotype. A characterization of these cells for expression of type C viral RNA and proteins demonstrated a correlation between tumorigenicity and virus expression. Several other human leukocyte lines with abnormal karyotypes did not always give rise to tumors.

MATERIALS AND METHODS

Human hematopoietic cells.—New B-lymphoblast lines established after infection with primate type C viruses: Human lymphoblast lines were established after type C virus infection of peripheral blood leukocytes or bone marrow obtained from EBV-seropositive normal human donors and adult donors with AML or from normal EBV-negative umbilical cord blood. The establishment and characterization of these lymphoblast cell lines have been described previously by Markham et al. (*7*). A bat lung fibroblast line (CCL88) was infected and used for the production of the type C retroviruses GALV or SSV, which in turn were used for the establishment of the cell lines of this study (*7*). In summary, the cell lines are B-lymphoblast lines by several criteria; e.g., all contain the EBV genome, positive erythrocyte–antibody–complement rosetting, and surface-bound immunoglobulin. These cells express variable amounts and types of viral RNA and proteins (*8*, *9*), but they generally fail to produce virus. Some cell lines were established spontaneously or with special growth conditions but without the use of exogenous virus.

Miscellaneous hematopoietic cell lines: The following human hematopoietic cell lines, which have been cultured for several years, were also used in this study: *1*) K-562, derived from the pleural fluid of a patient with chronic ML in blast crisis; *2*) NALM-1, derived from the peripheral blood of a leukemic patient; *3*) DHL-2, derived from the pleural fluid of a lymphoma patient; *4*) KG-1, derived from the peripheral blood of a patient with AML; *5*) U-43195, derived from the peripheral blood of a normal subject; and *6*) 8226, derived from the peripheral blood of a patient with multiple myeloma. Table 1 contains the references on these established cell lines.

Prior to their inoculation into animals, cell lines less than

8226	Multiple myeloma	Plasma cell	(*14*)	3/3	Aneuploid

[a] Tumorigenicity=No. of nude mice with tumors/No. of mice inoculated. All cell lines were inoculated sc at a cell concentration of 10^7/nude mouse.

6 months old were maintained in vitro as suspension cultures in RPMI-1640 medium supplemented with either 10 or 20% fetal bovine serum. All leukocyte lines were tested for the presence of mycoplasma at regular intervals by standard procedures (*15, 16*). Only mycoplasma-free cultures were utilized for tumorigenicity experiments.

Karyotype analysis.—Karyotype analysis was performed on leukocyte lines with the use of standard procedures and trypsin–Giemsa banding techniques (*17, 18*).

Tumorigenicity studies in nude mice.—Lymphoblast and other cell lines were tested for their ability to induce tumors in 6- to 15-week-old athymic BALB/c (*nu/nu*) mice (ARS/Sprague-Dawley, Division, The Mogul Corp., Madison, Wis.). After sc inoculation of 10^7 viable cells into the neck region, the mice were observed for the formation of tumors on a regular basis for a minimum of 6 weeks before an experiment would be considered negative for tumor growth. Tumors were removed and processed for histologic examination by fixation, thin sectioning, and hematoxylin–eosin staining. Results were considered positive for tumorigenicity when the cells formed a mass of at least 0.5 cm in diameter and also exhibited a progressive increase in size. A growth smaller than 0.5 cm was considered a nodule.

Detection of type C viral RNA and structural proteins.—Viral RNA was detected by molecular hybridization procedures, and viral p12, p30, and gp70 were detected by competition radioimmunoassay as described by Markham et al. (*8*).

RESULTS

The tumorigenicity and karyotype results for the 36 leukocyte cell lines are presented in tables 1–3. These cell lines consisted of 29 of the newly established B-lymphoblast lines, 21 were established after infection with a retrovirus, and eight were spontaneously established cell lines (*7–9*). Of these cell lines 23 were from normal donors and six were from patients with AML. In addition, seven previously established cell lines of various lineage were tested.

One of the three normal diploid B-lymphoblast lines from leukemic donors established after retrovirus infection formed a progressively growing tumor. Also, five of the 18 normal diploid B-lymphoblast lines from normal peripheral blood formed growing tumors. An example of a normal diploid karyotype of cells that produced progressive tumors is shown in figure 1. In contrast, the eight spontaneously transformed B-lymphoblast lines with normal diploid karyotypes did not form tumors. However, one of these lines formed a small, 0.5-cm tumor which persisted for several months without any further growth. Four of the seven previously established cell lines (LB$_{V}$-16A3, K562, KG-1, and 8226) exhibiting abnormal karyotypes formed progressive tumors.

Table 2.—*Tumorigenicity in nude mice of normal diploid human B-lymphoblast cultures*[a]

Cell source	Treatment	Subcutaneous tumors[b]		
		None	Regressive	Invasive
Peripheral blood (adult and cord blood)	Type C virus-initiated	6	7	5
	Spontaneous	4	0	1[c]
Adult leukemic peripheral blood	Type C virus-initiated	1	1	1
	Spontaneous	1	2	0

[a] B-lymphoblast cultures were initiated from normal or leukemic donors either after exposure to type-C retroviruses, GALV (*30*), or SSV (*31*), or spontaneously. Chromosomes were analyzed as described in "Materials and Methods."

[b] Mice were inoculated sc with 10^7 viable cells. All tests were performed in triplicates. None=no visible or palpable cell growth; regressive=small nodules (<0.5 cm in diameter) appeared but gradually regressed; invasive tumor=tumor reaching size >0.5 cm in diameter in at least 1/3 inoculated mice.

[c] Persisting tumor only.

Of the normal diploid B-lymphoblast lines established with type C viruses, such as GALV or SSV, 12 were tested for the presence of viral RNA and the structural proteins p12, p30, and gp70. Those results and correlations with tumorigenicity are presented in table 3. Of the six lines positive for viral RNA or proteins, four were tumorigenic. In contrast, only one of the six lines negative for virus expression was tumorigenic.

Examination of sections of the tumor formed by one of the karyotypically normal diploid lines showed a population of lymphoblasts that appeared homogeneous (fig. 2). No metastases of these lymphomatous tumors were observed. Tumors were removed, a cell suspension was obtained, and the cells were grown again in culture. Karyologic analysis involving trypsin–Giemsa banding techniques of cultured cells derived from the tumors again showed normal diploid

TABLE 3.—*Tumorigenicity in nude mice and expression of type C virus-related nucleic acids or proteins by normal diploid human B-lymphoblast cultures*

Cell line[a]	Virus expression[b]	No. of mice with tumors/No. of mice inoculated[c]

[c] NR=nodule regressed.

karyotypes and normal banding patterns (fig. 3). Ten of the normal diploid cell lines that formed nodules that regressed also exhibited normal diploid karyotypes.

The aneuploid cell lines (table 1) either formed progressive tumors or no tumors at all. Fresh leukocyte specimens from leukemic or normal donors did not form tumors (data not shown). These specimens included peripheral blood lymphocytes and other mononuclear cells treated with protein A or with pokeweed mitogen.

DISCUSSION

Previous studies by Nilsson et al. (*5*) have shown that normal diploid human lymphoid cell lines do not form subcutaneous tumors in nude mice. In agreement with this finding, in the present study the majority of normal diploid cell lines did not give rise to progressive tumors either. However, a significant number of our normal diploid B-lymphoblast lines formed lymphomatous masses. This is not necessarily in conflict with the finding of Nilsson and coworkers because in our study the five normal diploid cell lines that induced tumors were established after infection with primate type C oncogenic retroviruses, whereas the cells tested by Nilsson et al. were spontaneously established lines. The results suggest a correlation between tumorigenicity and the presence of type C viral information or expression in human B-lymphoblasts. One possibility that may explain these results is that the presence of retrovirus or of retrovirus proteins could cause further immunosuppression in nude mice. Several studies (*19–21*) have suggested that immunosuppression may follow retrovirus infection in a number of animals, and a more recent study has shown that a virion polypeptide from feline leukemia virus has immunosuppressive properties (*23*). A report by Giovanelli et al. (*6*) indicated that normal diploid human lymphoid cells, which fail to grow subcutaneously, formed tumors in immunologically privileged sites such as the brain; Watanabe et al. (*24*) reported that normal diploid lymphoblastoid cells gave rise to subcutaneous tumors in splenectomized nude mice that had received whole-body irradiation. The nude mouse has not been the only host system used for tumor formation by normal diploid cells. For example, Miyoshi et al. (*25*) demonstrated that antilymphocyte-treated newborn hamsters supported tumor formation of normal human leukocytes derived from peripheral blood of adults or from cord blood. Twelve lymphoblastoid cell lines established from these lymphoid tumors also exhibited a normal diploid karyotype. It is therefore clear that tumor masses can form in test animals in the absence of any detectable chromosome abnormality.

We do not know the mechanisms (immunologic and/or nonimmunologic) that favor or prevent tumor growth in the subcutaneous environment of the nude mouse and that contribute to the substantial variation in results from animal to animal. Factors such as origin of lymphoid cells, patient diagnosis, sex and age of the mouse, and cell concentration of the inoculum do not seem to account for these results alone. Immunologic factors may play an important role in lymphoid cell fate in the subcutaneous space of the nude mouse. The nude mouse does exhibit some immunologic function, such as immunoglobulin production (*26*) and natural killer cell activity (*27*). Nonimmunologic factors could also determine the fate of inoculated lymphoid cells. For example, factors in the subcutaneous microenvironment, such as nutrient availability and lymphoid cell interactions with host cells, could vary from mouse to mouse, which could explain the inconsistency in tumor "takes." Which, if any, of these mechanisms actually plays a role in inhibition of tumor formation or progression is not known.

The crucial question to be asked with regard to tumor formation by diploid cells in nude mice, is whether or not tumor growth, in either the brain or in subcutaneous space represents a true malignant neoplasm. Two useful criteria in the definition of cancerous growth are transplantability and metastasis. In other studies we observed that the human promyelocytic leukemia cell line HL-60 (*28*) could not be serially transplanted beyond one animal passage despite the clear leukemic nature of these cells (*29*). Moreover, metastases were not observed in any of the nude mice inoculated with aneuploid or diploid human leukemia leukocytes. It is clear then that a cell may be neoplastic and not be able to grow in nude mice and not exhibit features characteristic of neoplastic cells. Therefore, the use of nude mice for tumorigenicity testing must be viewed with caution.

Hormone Dependence of 7,12-Dimethylbenz[*a*]anthracene-Induced Mammary Tumor Growth: Correlation With Prostaglandin E$_2$ Content[1,2,3]

M. Katherine Foecking,[4] William E. Kibbey,[5,6] Hussein Abou-Issa,[5] Richard H. Matthews,[4] *and* **John P. Minton[5,7]**

ABSTRACT—Prostaglandin content in 7,12-dimethylbenz[*a*]anthracene-induced rat mammary tumors was correlated with growth responses to alterations in endogenous estrogen and prolactin. Prostaglandin E$_2$ (PGE$_2$) content varied inversely with tumor latency. Ovariectomy of tumor-bearing Sprague-Dawley rats resulted in regression of tumors in 90% of the castrated rats. PGE$_2$ content in tumors from ovariectomized rats was elevated twofold ($P<0.05$) compared to PGE$_2$ content in tumors from intact controls. Haloperidol treatment promoted tumor growth even after ovariectomy and returned tumor PGE$_2$ values to control levels. Tumors grouped by growth status irrespective of hormone status showed an inverse relationship between PGE$_2$ content and growth response.—JNCI 1982; 69:443–446.

PG stimulate bone resorption in the process of breast cancer metastasis (*1*). The pain due to bone metastases is relieved by levodopa, a prolactin release inhibitor, in patients with hormone-dependent primary breast cancer (*2*). These facts suggest that PG production in mammary cancer may be hormonally modulated. PG have been reported to mediate some prolactin actions in normal murine mammary tissue (*3–5*), and PG have been shown to vary in this tissue with the fluctuation of ovarian hormones in the estrus cycle (*6*).

The role of PG in the control of tumor cell growth has been investigated in vivo and in vitro, and the reports showed conflicting results. Exogenously applied and endogenously produced PGE have been reported to inhibit the growth of several different cell lines in vitro (*7–9*), and PGF$_{2\alpha}$ inhibited tumor growth in vivo (*10*). In contrast, inhibition of PG synthesis by indomethacin has been reported to inhibit tumor growth and cell proliferation in vivo (*11–13*), and PGF$_{2\alpha}$ promoted the initiation of proliferation in mouse fibroblasts in vitro (*14*).

The purpose of this study is to investigate the possibility that PG play some role in hormone-dependent mammary cancer by correlation of in vivo hormone manipulation effects to tumor growth and changes in PG levels that accompany it.

MATERIALS AND METHODS

Mammary tumors were induced by injection of a 1-ml emulsion containing 5 mg of DMBA (provided by Dr. Paul Schurr, The Upjohn Co., Kalamazoo, Mich.) into the tail veins of 50–55-day-old female Sprague-Dawley Cox:(SD) outbred rats (*15, 16*). The rats were maintained on standard laboratory chow and water ad libitum. Sprague-Dawley rats with DMBA-induced mammary tumors were also obtained from commercial sources (Hazleton Laboratories, Vienna, Va.). Hormone manipulations were begun on rats bearing 1 or more visible mammary tumors $>1.0\times1.0$ cm in size. A depletion in endogenous estrogen was accomplished by bilateral ovariectomy. Serum prolactin levels were elevated with haloperidol (*17*) injected daily for 4 consecutive days at a dose of 120 µg in 0.2 ml olive oil (*18*). Control rats received 0.2-ml injections of olive oil alone. The rats were killed on the 5th day by decapitation and the tumors were rapidly excised and frozen in liquid nitrogen (−196°C). Tumors were similarly excised from ovariectomized rats 5–11 days after surgery.

The growth response of the tumors to the various in vivo hormone manipulation treatments was measured with the use of vernier calipers. A regressing tumor was defined as one in which the sum of the length and width was decreased by at least 20% from the measurement taken at the beginning of the treatment period. A growing tumor was one in which length plus width increased 20% or more. If the change in length plus width was less than 20%, the tumor was considered stable in size.

The individual tumors, which were excised and frozen at the end of the treatment period, were pulverized, homogenized in 9 volumes of 50 mM Tris-HCl-44 mM EDTA solution (pH 7.5) at 4°C, with the use of a Potter-Elvehjem type tissue grinder with a Teflon pestle, and then acidified with 1 M citric acid. PG were extracted into cold redistilled ethyl acetate (MC&B Manufacturing Chemists, Cincinnati, Ohio) and subjected to purification by silicic acid column chromatography as described earlier (*19*). The fraction containing all the PGE was then used to determine PGE$_2$ by radioimmunoassay, according to Caldwell et al. (*20*). Antibody to PGE$_2$ was provided by Dr. Thomas Ferris, Department of Medicine, Ohio State University, Columbus, Ohio.

RESULTS

Administration of DMBA to Sprague-Dawley rats resulted in the appearance of mammary tumors from 2.5 to 11 months after exposure to the carcinogen. PG production was seen to vary with tumor latency, which is the time between DMBA administration and the appearance of the tumor. The PGE_2 content of the tumors is inversely related to tumor latency ($r=0.94$: table 1). Therefore, to eliminate complicating variables, we made experimental comparisons in tumors of matched latency in age-matched rats.

The response of mammary tumor PGE_2 content to hormone manipulations is shown in table 2. PGE_2 content was elevated approximately twofold in tumors from ovariectomized rats compared to PGE_2 content in tumors from intact rats ($P<0.05$). Ovariectomy results in a decrease in serum prolactin subsequent to depletion of estrogen since it is known that estrogen stimulates prolactin release (*18*). Tumors from rats treated with haloperidol showed similar PGE_2 levels to those in tumors from non-hormone-manipulated control rats. To determine if the effect of ovariectomy on PGE_2 levels was due primarily to the decrease in estrogen or the subsequent decrease in prolactin, we ovariectomized the rats and then treated them with haloperidol, so that serum prolactin levels would be maintained in the absence of estrogen. PGE_2 levels in tumors from these rats were not different from the levels in tumors from non-hormone-manipulated controls.

The modifications resulting from the various treatments resulted in alterations in the growth response of the DMBA-induced mammary tumors. Ovariectomy resulted in regression of tumors in 90% of the castrated rats. When the rats were treated with haloperidol after ovariectomy, tumor growth was maintained. Tumor growth was also maintained in haloperidol-treated intact rats.

The changes in tumor PGE_2 levels corresponded with their growth response to these treatments. In actively growing or stable tumors in intact rats, PGE_2 levels were 65±15 ng/g tissue. In intact rats treated with haloperidol, continued growth was accompanied by PGE_2 levels similar to those in tumors from intact rats not treated with haloperidol. The doubling of PGE_2 levels upon ovariectomy was accompanied by regression of the tumors. However, haloperidol treatment of ovariectomized rats resulted in continued growth of the tumor along with PGE_2 levels, which were very similar to those of the growing tumors from the intact non-hormone-manipulated rats. Whereas most of the tumors from the intact rats were found to be actively growing at the time of PG determination, in some tumors the growth rate had reached a plateau. To correlate tumor PGE_2 levels with the growth rate further, we classified tumors as growing, stable, or regressing (as described in "Materials and Methods"), without regard to hormone treatment. An inverse relationship between tumor growth and tumor PGE_2 content was observed (table 3). PGE_2 tissue content was highest in regressing tumors, intermediate in stable tumors, and lowest in growing tumors.

DISCUSSION

Our results show that PG content in DMBA-induced mammary tumors is inversely related to tumor latency. The loss of the ability of tumors from older rats to produce PG may be due to the age and hormonal status of the animals and/or the morphologic or the hormone characteristics of the tumors that appear at different times after DMBA administration. Investigators have shown that tumors that appear sooner after induction by DMBA show a greater degree of hormone responsiveness than tumors with longer latent periods (*18*). However, the differences in PG levels between young and old tumors do not appear to be due to the characteristic of hormone dependence or independence. We have found that PGE_2 is produced at approximately equal rates by hormone-dependent and hormone-independent human and rat mammary tumors (Kibbey WE, Foecking MK: Unpublished observations). Furthermore, Rolland et al. (*12*) reported that steroid-receptor-negative human mammary tumors produce more PG than do steroid-receptor-positive tumors. Older rats with longer latent periods, however, demonstrate a high rate of spontaneous regression, and their tumors are often morphologically classified as benign adenomas (*18*). Therefore, the decline in PG production in older tumors may be a function of the morphologic characteristics of the tumors. The interpretation of comparisons between benign tumors and adenocarcinomas is problematic due to the differences in the degree of differentiation of the two types of tumors. Rolland reported that tumors with a lower degree of differentiation synthesize more PG than those with a higher degree of differentiation (*21*). The observation that PG content is lower in benign tumors than in adenocarcinomas but is elevated in regressing adenocarcinomas is not necessarily a contradiction, because the process that takes place during regression in in vivo tumors is not identical to the redifferentiation observed in cells in culture. Therefore, an awareness of the variation of morphology, hormone responsiveness, and PG production with age and tumor latency is necessary for proper experimental design when hormone effects on PG production are studied in the DMBA-induced mammary tumors in rats.

The increase of PGE_2 levels in the tumors from ovariectomized rats compared to PGE_2 levels in tumors from intact, nonovariectomized rats suggests that hormones that are depleted by ovariectomy are involved in the regulation of PG synthesis in cancerous mammary tissue. This postulate is consistent with the work of Knazek et al. (*6*), who showed that PGE_2 synthesis in normal murine mammary tissue varies with the stage of the estrus cycle, which suggests that PG production by mammary tissue is sensitive to fluctuations in ovarian hormones. The effect of hormonal changes in PGE_2 levels corresponds with the growth response to the alterations in hormone levels. The increase in tumor PGE_2 levels after ovariectomy of the tumor-bearing rats is accompanied by regression of these tumors. Tumor growth is observed in intact rats. When prolactin levels are elevated in intact rats by haloperidol treatment, the continued growth is accompanied by PGE_2 levels similar to the levels in tumors from the intact controls. When prolactin levels are maintained in ovariectomized rats, the tumor growth is also maintained, and the observed PGE_2 levels are not different from levels in tumors from nonmanipulated intact controls. Thus prolactin overcomes the effect of ovariectomy on tumor growth response and PGE_2 levels. These results are consistent with the work of Meites et al. (*18, 22*), who showed that the increase of serum prolactin by haloperidol promotes tumor growth even in the absence of the ovaries, which implies that prolactin may be more important than estrogen in the hormonal control of DMBA-induced mammary tumors. Pearson and co-workers (*23, 24*) also reported that prolactin is the major growth stimulant in DMBA-induced tumors and that estrogen enhances tumor growth through the stimulation of prolactin release. In contrast, our results are inconsistent with the report of Sinha et al. (*25*), who found that the stimulation of mammary tumor growth by prolactin is dependent on the presence of ovarian hormones, primarily of estrogen.

The causal connection between hormone manipulations and changes in PGE_2 levels has not been established. Prolactin effects may be mediated by PG in normal mammary tissue (*2–5*). On the basis of our results, the relationship between prolactin and PG in cancerous mammary tissue appears to be an inverse relationship in which prolactin suppresses PG synthesis. Future investigations will determine whether greater increases in serum prolactin would result in a depression of PGE_2 levels or whether the PGE_2 level observed in growing tumors is a basal level for that tissue. Work is in progress in our laboratory to further characterize the relationship between alterations in serum prolactin, separately and in combination with alterations in ovarian hormones, and the effects on PG production.

The inverse relationship between PGE_2 content and tumor growth rates (table 3) indicates that PG may be functionally involved in the regulation of tumor growth. Our results showed that regressing tumors exhibit a high PGE_2 content, whereas actively growing tumors exhibit low PGE_2 levels and static tumors exhibit intermediate PGE_2 levels. These results are consistent with those of previous reports, which showed that inhibition of tumor growth is influenced by PG (*9, 10, 26*). PG have been shown to stimulate adenylate cyclase activity in many cells including mammary cells (*27, 28*) and thus increase their intracellular cAMP content. cAMP has been reported to be involved in mammary tumor regression (*29–31*). Recent studies have also shown that growing DMBA-induced mammary tumors have lower cAMP levels and adenylate cyclase activities than regressing tumors, whereas static tumors have intermediate values (*31*). In view of these studies it is possible that the action of PG on tumor growth behavior is expressed via regulation of cAMP production. Further studies are in progress in our laboratory to correlate PGE_2 and cAMP levels in growing, static, and regressing mammary tumors.

Comparison of Ovariectomy and Retinyl Acetate on the Growth of Established 7,12-Dimethylbenz[*a*]anthracene-Induced Mammary Tumors in the Rat[1,2,3]

Philippe Gandilhon,[4,5] **Réjean Melancon,**[4] **Jean Djiane,**[6] *and* **Paul A. Kelly**[4]

ABSTRACT—Prolonged exposure to retinyl acetate (RA) in the diet inhibits the development of 7,12-dimethylbenz[*a*]anthracene (DMBA)-induced mammary cancers in rats. The effectiveness of RA was examined when given 6 months after the administration of DMBA. Noninbred female Sprague-Dawley rats with DMBA-induced mammary tumors were divided into 3 groups and treated for 4 weeks as follows: Group 1 served as controls, group 2 was ovariectomized, and group 3 received 328 mg RA/kg diet. Ovariectomy (OVX) markedly reduced both the number and size of the tumors. RA administration failed to induce any significant regression in tumor number but significantly retarded tumor growth when compared to tumor growth in group 1 controls. The levels of estradiol, progestin, and prolactin (PRL) receptors were significantly reduced after OVX, whereas only the levels of PRL receptors declined significantly after RA administration. Circulating progesterone concentrations were not affected in the RA-treated group but the plasma PRL level was significantly increased. The present studies show that if treatment with RA is delayed until 6 months after carcinogen administration, the protective effect of RA can still be observed although its effectiveness is less dramatic than when it is administered earlier.—JNCI 1982; 69:447–451.

Retinoids are known to be involvd in the induction or enhancement of cellular differentiation, and the use of retinoids in the prophylaxis of cancer may therefore represent a physiologic approach to arrest the process of carcinogenesis (*1*). Retinoids have been shown to be highly effective in preventing mammary cancer induced in the rat by DMBA (*2-4*) or MNU (*5-7*). In addition, it has been reported that dietary vitamin A acetate (RA) supplements can inhibit the late phase (growth and development of palpable tumors from transformed cells) of DMBA-induced (*3*) and benzo[*a*-]pyrene-induced (*8*) mammary carcinogenesis since RA administration can be initiated 1 week after carcinogen administration or can be delayed beyond 1 week with no alteration in the chemoprotective effects of RA. These observations suggest some role of the retinoids in controlling growth of transformed cells. The aim of the present study is to determine the ability of RA to inhibit mammary tumor growth when retinoid treatment is delayed in rats bearing established DMBA-induced tumors. In addition, the effect of an endocrine therapy (OVX) is compared with the effect of RA treatment on established tumor growth and hormone receptor levels.

MATERIALS AND METHODS

Animals and treatments.—Noninbred female Sprague-Dawley rats (Canadian Breeding Farms, St. Constant, Quebec) were given a single intragastric dose of 10 mg DMBA in 0.5 ml sesame oil at 50–55 days of age. All animals were housed 2 per cage in a room controlled for light cycle (lights on between 5 a.m. and 7 p.m.) and were allowed free access to drinking water and Purina Rat Chow.

Tumors began to appear about 1 month after DMBA administration. Six months after DMBA administration, 60 rats bearing DMBA-induced mammary tumors were selected and divided into 3 groups of 20 animals each. Each group was adjusted to a similar tumor number (70–72 tumors/group) and to a similar tumor area (145–150 cm^2/group). The first group served as control, the second group underwent OVX and the third group received RA. To treat animals with retinoid, we blended RA into the stock diet in the form of stable gelatinized beadlets at a concentration of 328 mg RA/kg diet, which corresponded to a daily intake of approximately 5 mg. Control rats were fed gelatinized beadlets without RA. All rats were palpated once a week for mammary tumors, and the number of tumors per rat was recorded. The two largest perpendicular diameters of each tumor were measured with calipers, and the product of these diameters was used as an estimate of tumor size. This value was expressed as the average tumor area (cm^2) per tumor. Tumor development was followed up to 5 weeks. The body weight of each animal was recorded at the beginning and at the end of the 4-week observation period. All animals were decapitated between 9 and 11 a.m. on the last day of the 4-week period. Trunk blood was collected in heparinized beakers. After separation by centrifugation, plasma was stored at −20°C until hormones were assayed. The tumors were removed immediately after the animals were decapitated. They were frozen and stored at −80°C until receptor studies were performed. Some tumor fractions were fixed in Bouin's fluid for histologic diagnosis.

Hormone solutions.—[^{3}H]R2858 (87 Ci/mmol) and [^{3}H]-R5020 (87 Ci/mmol) were obtained from New England Nuclear Corp., Boston, Mass., and the corresponding unlabeled steroids were synthesized at the Roussel Research Center, Romainville, France. Dexamethasone was purchased from Sigma Chemical Co., St. Louis, Mo. Stock solutions of the unlabeled steroids were kept at 2–4°C at a concentration of 4 m*M* in ethanol. The desired steroid solutions were prepared by serial dilution with buffer B [10 m*M* Tris-HCl (pH 7.4), 1.5 m*M* EDTA, and 10 m*M* thioglycerol]. The final concentration of ethanol in the assays never exceeded 0.2%, a concentration that does not affect steroid binding.

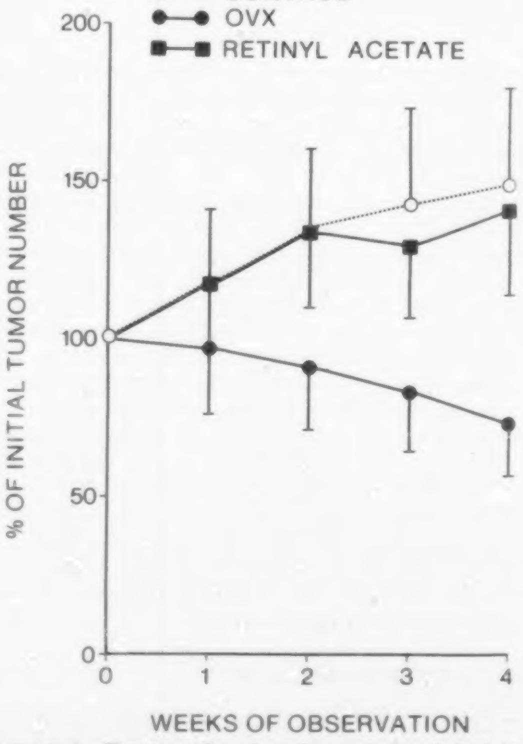
We obtained hGH (lot #HS-2160E; 1.71 U/mg), oPRL (lot #NIH-P-S13; 30 U/mg), and materials for the RIA of rat PRL from the National Pituitary Agency, National Institutes of Health, Bethesda, MD.

Preparation of cytosol and membrane fractions.—After thawing, tumors or tumor fractions were weighed and homogenized in 6 volumes (wt/vol) of buffer A [25 m*M* Tris-HCl (pH 7.4), 1.5 m*M* EDTA, 10 m*M* thioglycerol, and 10% glycerol) with the use of a Polytron PT-10 homogenizer at a setting of 5 for 2 or 3 periods of 10 seconds with an interval of 10 seconds for cooling. The homogenate was then centrifuged at 1,500×*g* for 15 minutes, and the resulting supernatant centrifuged at 105,000×*g* for 90 minutes to obtain the cytosol (supernatant fraction). All steroid-binding assays were performed with freshly prepared cytosol fractions. The 105,000×*g* pellet was resuspended in 25 m*M* Tris-HCl (pH 7.4) and 10 m*M* $MgCl_2$ with a Teflon and glass homogenizer and stored at −20°C until PRL-binding assays. Protein concentrations were measured with BSA as standard (*9*).

Estrogen and progesterone receptor levels.—[^{3}H]R2858 binding and [^{3}H]R5020 binding were measured with the use of the protamine sulfate and DCC assays, respectively (*10*). In the standard assay, 0.2-ml aliquots of the cytosol were incubated with 0.1 ml of 5 n*M* [^{3}H]R2858 or 8 n*M* [^{3}H]R5020 in the presence or absence of a 100-*M* excess of the unlabeled steroid for 5 hours at 25°C or for 16–20 hours at 0–4°C. Time-course studies have been performed, and the times utilized represent equilibrium or steady-state conditions. An excess of dexamethasone was always added to the [^{3}H]R5020 solution to saturate all glucocorticoid receptors. For the [^{3}H]R5020-binding assay, unbound steroids were removed by incubation for 10 minutes at 0–4°C with 0.3 ml of 0.5% Norit-A–0.05% Dextran T-70 (DCC) in buffer B and centrifugation at 2,000×*g* for 10 minutes at the same temperature. Then 0.3-ml aliquots of supernatant were removed. After addition of 8 ml of Aquasol, the radioactivity was measured in a Beckman liquid scintillation spectrometer at a 40% counting efficiency. For the [^{3}H]R2858-binding assay, 0.3 ml of a 2% protamine sulfate solution in buffer B was added and the tubes incubated for 10 minutes. The resulting precipitate was filtered and washed in buffer B, and the filters were counted. The extent of specific binding was obtained by subtraction of nonspecific radioactivity from total bound radioactivity.

Dissociation of endogenously bound PRL.—Since a large portion of PRL still remained bound to the receptors at the end of the membrane fraction preparation, it was necessary to remove endogenously bound PRL to measure total PRL receptor levels (*11*). We added 0.5 ml of 3 *M* $MgCl_2$ to 1.5 mg of DMBA-induced mammary tumor membrane protein in 12×75-mm glass tubes. The tubes were mixed on a vortex and after 3 minutes, 3.5 ml of the assay buffer [25 m*M* Tris-HCl (pH 7.4), 10 m*M* $MgCl_2$, and 0.1% BSA] was added to each tube. The tubes were centrifuged at 2,300×*g* for 15 minutes, and the resulting supernatant was aspirated. The pellets were resuspended in 0.5 ml of the assay buffer and binding studies were performed.

PRL receptor levels.—It was shown previously that ^{125}I-labeled hGH binds with the same affinity and specificity as ^{125}I-labeled oPRL to membrane fractions prepared from PRL-responsive tissues. We used ^{125}I-labeled hGH for PRL binding since labeled samples of this hormone have proved more stable than labeled PRL. A modification of the method of Hunter and Greenwood (*12*), in which 500 ng chloramine-T and 5 μg hGH were incubated for 3 minutes at 23°C, was employed to iodinate hGH (*11*). The iodinated hormone was purified on a column of Sephadex G-75 (0.9×100 cm), and the tubes of radioactivity comprising the protein peak were diluted in assay buffer and could be stored for as long as 3 weeks at 4°C. Specific activities, as calculated by isotope recovery, ranged between 75 and 95 μCi/μg. The integrity of the iodinated hGH was verified after each iodination with the use of a laboratory standard receptor preparation. At

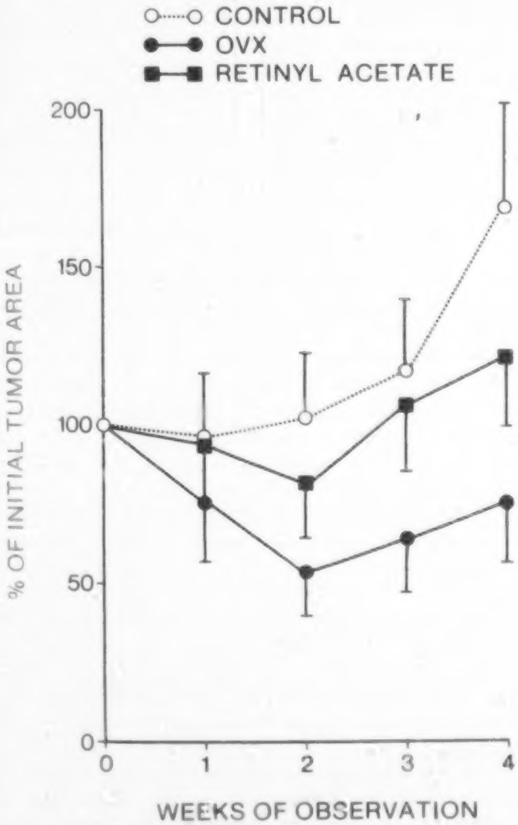


TEXT-FIGURE 1.—Tumor numbers throughout a 4-wk period of observation. Tumor numbers are presented as percent of the initial (time 0) values for each group: control, 3.32±0.46; OVX, 3.53±0.54; and RA, 3.55±0.41. *Vertical bars* show SEM.

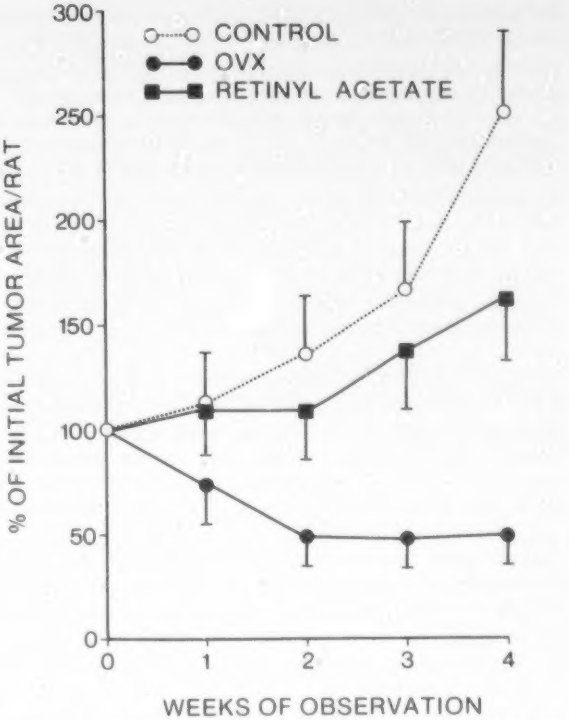
the concentration of the mammary gland receptor used (300 μg), at least 40% of the iodinated hGH was specifically bound before the tracer was considered acceptable.

DMBA-induced mammary tumor membranes (300 μg) were incubated with approximately 100,000 cpm ^{125}I-labeled hGH both in the presence and absence of an excess (1 μg) of unlabeled oPRL. Specific binding was calculated as the difference between the cpm bound in the absence and presence of excess unlabeled hormone and was expressed as a percentage of the total radioactivity added to the tube.

Measurement of plasma PRL and progesterone and calculations.—Plasma PRL was measured by a double-antibody RIA with the use of rat hormones and rabbit antisera. Plasma progesterone concentrations were determined by specific double-antibody RIA. Plasma was extracted with benzene. Assays were performed with the use of antibodies developed against progesterone-12-(*O*-carboxymethyl)-oxime. ^{125}I-labeled progesterone-12-(*O*-carboxymethyl)-oxime tyrosine methyl ester was used as labeled tracer (*13*). RIA data were analyzed with the use of a program based on model II of Rodbard and Lewald (*14*). Receptor assays were calculated with the use of a program developed in this laboratory. Calculations were performed with Hewlett-Packard 9845T desk-top calculator. Statistical significance was determined by Student's *t*-test, Duncan-Kramer multiple range test (*15*), or the χ^2 test. All data presented are means plus or minus standard errors of the means. Each assay was performed with at least duplicate determinations.



TEXT-FIGURE 2.—Tumor area throughout a 4-wk period of observation. Tumor areas are presented as percent of initial (time 0) values for each group: control, 1.91±0.28 cm^2; OVX, 1.99±0.28 cm^2; and RA, 2.12±0.27 cm^2. *Vertical bars* show SEM.



TEXT-FIGURE 3.—Total tumor area per rat throughout a 4-wk period of observation. Tumor area per rat is presented as a percent of initial (time 0) values for each group: control, 6.34±0.94 cm^2/rat; OVX, 7.12±0.99 cm^2/rat; and RA, 7.51±0.95 cm^2/rat. *Vertical bars* show SEM.

RESULTS

The response in tumor number to OVX and RA treatment is shown in text-figure 1. The number of tumors at time 0 was 63 (control), 68 (OVX), and 71 (RA treatment). OVX significantly reduced tumor number (27%; $P<0.01$) compared to the number of tumors in the control group which increased steadily and reached 149±29% of the initial tumor number at the end of the experiment. RA administration failed to induce any significant regression in tumor number, although there was a slight regressing effect during the last 2 weeks of the treatment.

The average tumor size (text-fig. 2) increased only slightly during the first 3 weeks in control animals, but it increased sharply (to 168%) at the 4th week of observation (from 1.91±0.28 cm^2 to 3.2±0.3 cm^2). During the first 2 weeks of treatment, OVX induced a maximum regression (to 53%) in tumor size which was 1.99±0.28 cm^2 at time 0, whereas the effect of RA was less pronounced (only a 19% decrease). During the last 2 weeks of the observation, tumors began to grow again in both the RA-treated and OVX-treated groups; however, at the end of the treatment period, tumors were smaller (1.5±0.2 cm^2) in OVX-treated animals than in the RA-treated group (2.5±0.2 cm^2) and both groups had tumors significantly smaller than those of controls ($P<0.05$). When tumor numbers and tumor size are combined and the results are expressed as the average tumor area per rat, the effects of treatment become clearer (text-fig. 3). There was a steady increase of initial tumor size to 251% in the control animals and the effect was most pronounced in the 3rd and 4th weeks. OVX induced a regression in tumor size, which was maximum at 2 weeks (to 51% of control values; $P<0.01$) after which growth was stabilized. RA retarded tumor growth when compared to tumor growth in controls, and the area increased to only 162% of control values at the end of the 4-week treatment period ($P<0.05$ compared to control).

Table 1 shows a subdivision of the tumor growth into those regressing tumors (<50% of initial size), static tumors (between 50 and 110%), and growing tumors (>10% increase). Two-thirds of the tumors in OVX-treated rats regressed ($P<0.001$; χ^2 analysis), whereas the ratio of regressing tumors in the RA-treated group was three times higher than that in controls ($P<0.03$; χ^2 analysis).

Specific binding of [^{3}H]R2858, [^{3}H]R5020, and ^{125}I-labeled hGH to tumors from treated animals is summarized in table 2. OVX significantly reduced the levels of estradiol and progesterone receptors ($P<0.01$), whereas RA treatment did not significantly affect steroid receptor levels. Both treatments significantly reduced the PRL receptor levels ($P<0.01$): OVX resulted in a 79% decline in PRL receptor levels ($P<0.01$), whereas the RA diet resulted in a slight but equally significant (21%) decline of PRL binding. If only regressing tumors are considered for PRL receptor levels, there was no significant difference in the RA-treated group compared to the control group (7.0±0.6 and 7.7±1.3%, respectively; data not shown).

Plasma progesterone and PRL levels at the time of death are shown in table 3. RA significantly increased circulating PRL concentrations ($P<0.01$) but did not affect plasma progesterone levels.

TABLE 1.—*Response to treatments expressed as percent of regressing, static, or growing tumors*

Group	Total No. of tumors	Total tumor growth, %		
		Regressing[a]	Static[b]	Growing[c]
Control	98	5.10	5.10	89.80

Group	No. of animals	ng/ml ± SEM	
		Progesterone	PRL
Control	19	4.91±1.23	14.09±2.94
OVX	19	0.34±0.05[a]	6.39±0.91[a]
RA	20	5.36±1.22	39.29±9.14[a]

[a] $P<0.01$, when compared to control.

No significant differences were observed in body weights between controls and either of the treated groups, which suggests an absence of toxic effect of RA. All tumors examined histologically were adenocarcinomas.

DISCUSSION

RA feeding has previously been reported to suppress the development of carcinogen-induced cancers in rats (*3–5, 7*). However, this approach had been extensively used only in the prevention of experimental mammary tumorigenesis. The specific role of RA in the regression of established DMBA-induced mammary tumors or a possible influence of this retinoid on hormonal factors regulating tumor growth has not previously been reported.

DMBA-induced rat mammary carcinogenesis was significantly inhibited by the chronic administration of a dietary supplement of RA beginning 1 week after carcinogen administration (*3*). In the present study, we have shown that if treatment with RA was delayed for 6 months after carcinogen administration and then a dose of retinoid sufficient to assure an intake of 5 mg per day was given, there was a lack of any substantial protective effect on tumor induction. As expected, OVX remained effective in inhibiting mammary carcinogenesis, although its effectiveness was less dramatic than that in animals with younger tumors.

Very little information is available on the ability of RA to reduce DMBA-induced mammary tumor growth. McCormick et al. (*3*) found that 12% of DMBA-induced mammary tumors regressed spontaneously in Lewis rats as compared to 29% in the retinoid-treated groups. In the present study in Sprague-Dawley rats, only 5% of the tumors regressed in controls versus 15% in RA-treated rats ($P<0.03$). Moreover, we have shown that a short dietary exposure to retinoid reduced tumor growth. The effect on tumor number was most noticeable in the first 2 weeks, and the effect on tumor area was more apparent in the last weeks of observation. However, when one compares the effectiveness of RA to that of OVX, the endocrine therapy clearly remains superior to the retinoid treatment. Although several reports have noted that vaginal smears from rats fed retinoid showed normal estrous cycles (*3, 4*), the effect of RA on circulating progesterone levels and steroid binding in the tumors has not been previously reported. Our data show that RA feeding did not alter circulating progesterone levels nor steroid binding to DMBA-induced mammary tumors, which suggests that the ability of RA to limit tumor growth in the rat is not mediated by an alteration of ovarian function, or tumor responsiveness to estrogen or progesterone.

Welsch et al. (*7*) reported a synergistic effect of chronic PRL suppression and retinoid treatment in the propylaxis of MNU-induced mammary tumorigenesis in female Sprague-Dawley rats. In the present study, an elevated level of circulating PRL in the RA-treated group could explain the failure of this treatment to reduce tumor number. There was a slight decline in PRL receptor levels in the RA-treated group in which a limited effect on tumor growth was observed, which suggests a possible direct effect of the retinoid on tumor membranes. Specific retinoic acid-binding proteins have been reported in the cytosols of mammary gland as well as in carcinogen-induced mammary tumors, and an increased relationship between steroid receptors and retinoid receptors in mammary tumors has been noted (*16*). This fact, coupled with the failure of RA to alter the ovarian function in rats, is in agreement with an hypothesis of direct cellular effects. Moreover, Lotan and Nicolson (*17*) have shown that the growth of a considerable number of both transformed cells and tumor cells (which form rat DMBA mammary adenocarcinoma cells lines) could be inhibited in vitro by retinoids, which suggests that the antitumor activity of retinoids observed in vivo is at least partly due to direct inhibition of cell proliferation. The reduced RA effect in the present report might be due to a diminished cellular sensitivity to retinoids in tumors from animals 6 months after DMBA administration.

The present study demonstrates that RA when administered to animals in advanced stages of the disease remains effective in inhibiting established tumor growth, but the effectiveness of RA is reduced compared to the effectiveness of RA administered at earlier periods of tumor development.

Growth and Differentiation of Hyperplastic Outgrowths Derived From Mouse Mammary Epithelial Cells Transformed in Organ Culture [1, 2, 3]

Nivedita Ganguly, [4, 5] **Ranjan Ganguly,** [4, 5] **Nozer M. Mehta,** [4] *and* **Mihir R. Banerjee** [4, 6, 7]

ABSTRACT—Potentially neoplastic outgrowths of BALB/c mouse mammary hyperplasia(s) (MH) derived from 7,12-dimethylbenz[a]anthracene-transformed epithelial cells in organ culture were characterized for responses to the hormones normally required for morphogenesis and functional differentiation of the mammary tissue. In a new culture model of the gland-free mammary fat pad, DNA synthesis in the MH outgrowths increased to a single peak during 6 days of incubation in a serum-free medium containing insulin, prolactin, aldosterone, and cortisol. The rise in DNA synthesis was accompanied by increased cell number and lobuloalveolar morphogenesis filling 50–70% of the fat pad; the rate of growth was variable among the MH outgrowth lines. Certain MH tissue showed some growth response in medium with aldosterone, cortisol, or estrogen, and progesterone in the presence of insulin. The hormone mixture insulin–prolactin was conducive to maximal growth, which suggested an altered sensitivity of the MH outgrowths to the mammogenic steroid hormones. Functional differentiation in the MH outgrowths was assessed in vivo by determination of the casein messenger RNA (mRNAcsn) levels measured by a specific complementary DNA probe. In MH-1 and MH-5 outgrowth lines, mRNAcsn was measurable in lactating hosts. In MH-9 outgrowth essentially the same concentration of mRNAcsn was present both in virgin and lactating hosts. Although mRNAcsn was present in MH outgrowths in lactating hosts, the concentration of the mRNA was only 0.056–0.88% of that present in the lactating host's own mammary gland. Virtually no mRNAcsn was measurable in the mammary tumors, regardless of the endocrine environment of the host animal. The results indicate a transformation-associated altered pattern of mammary cell-specific gene expression.—JNCI 1982; 69:453–463.

Recent studies have established that the murine mammary parenchyma in an isolated whole organ in vitro can mimic the stages of mammogenesis, functional differentiation, and alveolar regression (involution) in a chemically defined medium supplemented with hormones (*1–3*). With the use of this unique culture model of the whole mammary organ, it has been demonstrated (*4–6*) that the carcinogenic hydrocarbon DMBA can induce neoplastic transformation of the epithelial cells in the gland in vitro and that the process is associated with appearance of a type of dysplasia referred to as "NLAL." The NLAL are sustained in a hormone-deficient medium, which suggests that the alveolar epithelium in these lesions exhibits a state of transformation with respect to its hormonal requirement. DMBA apparently is metabolized by the mammary cells in organ culture, because incubation of the glands in medium with the hydrocarbon results in covalent binding of the carcinogen with cellular DNA (*6*). Therefore, the molecular interactions of DMBA with mammary gland in vitro is characteristic of similar interactions associated with the transforming action of DMBA in other cell types (*7, 8*). Subsequent studies have shown that a variety of oncogenic chemicals, direct-acting as well as those requiring metabolic activation, also induced NLAL in the mammary organ under similar culture conditions (*9, 10*). The incidence of NLAL, induced by a low concentration of procarcinogen, is preventable by a retinoid, a vitamin A analogue (*11*), which has been found to inhibit mammary tumorigenesis in rats (*12, 13*).

Studies in our laboratory have indicated that the transformed mammary epithelial cells (including those in NLAL) in the mammary organ in culture include potentially neoplastic cells (*14*). After transplantation into gland-free mammary fat pads of syngeneic female mice, the transformed cells initially produce hyperplastic lobulo-alveolar outgrowths in virgin hosts. Subsequently, mammary tumors appear in these MH outgrowths. Serial transplantation studies further showed that the pattern of sequential appearance of MH outgrowths and mammary tumors is analogous to that of the preneoplastic HAN (*15*). Thus the mammary epithelial cells transformed in vitro by DMBA mimic the multistage genesis of murine mammary neoplasia in vivo (*16–19*). This accomplishment of neoplastic transformation of the mammary epithelial cells in an isolated whole organ in culture presents a unique in vitro model for assessment of responses of the epithelial cells to various exogenous agents, including potential carcinogenic and chemopreventive chemicals. This model then prompts a detailed analysis of the characteristics of the cells transformed in vitro. This report presents the results of the studies on responses of different MH outgrowth lines to the regulatory hormones needed for morphogenetic and functional differentiation of the normal mammary glands of the mouse.

Abbreviations used: cDNAcsn=complementary DNA to 15S mouse casein messenger RNA; DMBA=7,12-dimethylbenz[*a*]anthracene; HAN=hyperplastic alveolar nodule(s); [^{3}H]dThd=tritiated thymidine; MH=mammary hyperplasia (hyperplastic); mRNAcsn=casein messenger RNA; NLAL=nodule-like alveolar lesions; R_0t=moles of ribonucleotides·sec·L^{-1}; $R_0t_{1/2}$=R_0t needed to reach 50% hybridization; TCA=trichloroacetic acid.

MATERIALS AND METHODS

Animals.—BALB/cAnN mice obtained from the National Cancer Institute were used.

MH outgrowth lines.—The four MH outgrowth lines used in the present studies were derived from the mammary epithelial cells transformed by DMBA in an in vitro carcinogenesis model of the whole mammary organ (*15*). The MH outgrowth lines were maintained by serial transplantation with the use of the standard procedure (*20*) into gland-free inguinal (fourth) mammary fat pads of syngeneic virgin hosts. The origin and biologic characteristics, including the tumorigenic potential of the MH outgrowth lines, have been recently described (*15*) and are summarized in table 1.

Proliferation of MH outgrowth lines.—The rate of cell proliferation in the MH outgrowth lines was measured during growth of the implant in the gland-free mammary fat pad in vivo and in vitro. In vivo cell proliferation: Small pieces of the MH tissues were transplanted with the use of the standard procedure (*20*) into the gland-free inguinal (fourth) mammary fat pads of 3-week-old syngeneic mice. At different times the entire inguinal mammary fat pad was isolated and stained with alum carmine, and the total area of the fat pad occupied by the outgrowth tissue was determined microscopically (*21*).

In vitro cell proliferation: Previously, we have observed that HAN tissue implanted into the gland-free mammary fat pad is capable of spatial proliferation in vitro filling the fat pad in a chemically defined medium that contained appropriate hormones (*22*). This gland-free mammary fat pad organ culture procedure was used to measure the growth characteristics of the MH lines and their responses to the growth-promoting hormones in a controlled in vitro environment. In these studies pieces of MH outgrowth tissue were first transplanted into the gland-free mammary fat pads (fourth) of the 3-week-old female syngeneic mice. According to the standard procedure (*22, 23*) the whole fat pad, which carried the MH tissue, was excised on a Dacron raft 3 weeks later and incubated in Waymouth's medium in the presence of a 95% O_2–5% CO_2 atmosphere. The rate of DNA synthesis, increase in cell numbers, and percent area of the fat pad filled by the MH tissue during a 6-day incubation in medium with combinations of insulin, prolactin, aldosterone, cortisol, estrogen, and progesterone were determined for measurement of growth. Procedures used for determination of each of these parameters are described in legends of appropriate text-figures.

Expression of functional differentiation.—Accumulation of mRNAcsn in different MH outgrowth lines and their tumors in vivo was used as a measure of functional differentiation. MH tissues were transplanted into the gland-free inguinal (fourth) mammary fat pads of 3-week-old BALB/cAnN female mice, and 10–12 weeks later the gland-free fat pads carrying the outgrowth tissue were collected from the virgin hosts. To measure the responses of the MH outgrowths and their tumors to the lactogenic hormone stimulation, we mated 9-week-old virgin host animals carrying the different outgrowth lines with BALB/c males (6 wks after transplantation). After the normal period of gestation, the fat pads carrying the MH tissues were collected from post-partum mice on the fifth day of lactation. In some cases tumors appeared in MH outgrowths carried in lactating hosts, and these tumors were also collected for measurement of functional differentiation. Until the animals were killed, the lactating mice were allowed to nurse their pups.

TABLE 1.—*Characteristics of DMBA-induced MH lines*[a]

MH lines	Morphology	Animals with tumors, %	Latent period of tumor incidence, wk	Mammary tumor type
MH-1	Lobulo-alveolar	30–35	20	Lobular
MH-3	Lobulo-alveolar	20–25	20	Lobular
MH-5	Mixed lobulo-alveolar ductal	45–50	25–30	Lobular
MH-9	Lobulo-alveolar	80–85	10–15	Lobular

[a] For further detail, *see* (*14*) and (*15*).

Nucleic acid hybridization: Total RNA from the MH, HAN-D8, and the mammary tumors was isolated by the phenol–chloroform method (*24*). Purification of 15S mRNAcsn and synthesis of a [^{3}H]-labeled cDNAcsn to the mRNAcsn were done as previously described (*25–27*). Concentration of the mRNAcsn in the total RNA of different mammary tissues was determined by RNA excess hybridization to the cDNAcsn probe (*25–27*). Test RNA's were incubated with [^{3}H]cDNAcsn probe (500 cpm; 4×10^6 cpm/µg) at 68°C for various times in a buffer containing 0.6 *M* NaCl, 10 m*M* HEPES[8] (pH 7.0), and 2 m*M* Na_2EDTA. At the end of the incubation the reaction mixtures were adjusted to 0.1 *M* sodium acetate (pH 4.5), 0.2 *M* NaCl, and 1.2 m*M* $ZnCl_2$. S_1-nuclease was added at 1,000 U/ml, and the reaction mixtures were incubated at 37°C for 2 hours. S_1-nuclease-resistant cDNA–RNA hybrids were precipitated on filters (Millipore Corp., Bedford, Mass.), and radioactivity was determined by liquid scintillation spectrometry. S_1-nuclease-resistant radioactivity in the reactions without any RNA was considered as background and was subtracted from all values. The mRNAcsn concentration in test RNA was determined as follows: $Rot_{1/2}$ of pure mRNAcsn: $Rot_{1/2}$ of test RNA×100.

RESULTS

Proliferation of MH Outgrowth Cell Lines in Gland-Free Mammary Fat Pads In Vitro

The whole gland-free mammary fat pad culture model was used to measure the growth rate of the MH lines in an in vitro controlled environment. MH outgrowth lines were derived from the mammary cells transformed by DMBA, apparently during lobulo-alveolar growth of the gland in the culture medium containing the hormones insulin, prolactin, aldosterone, and cortisol. Accordingly, the growth rate of the MH outgrowth lines in vitro was also measured in the presence of the same hormone mixture in the culture medium.

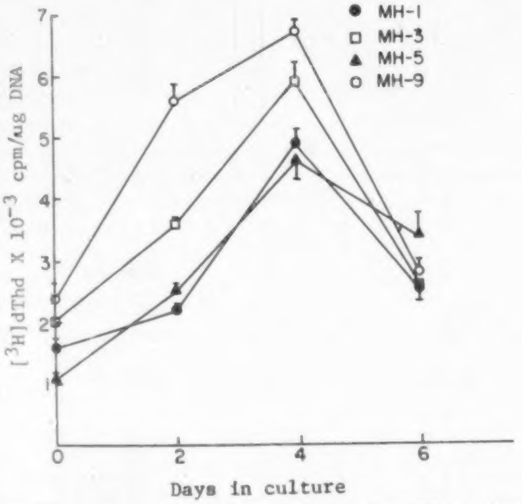
[8] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

DNA Synthesis in MH Outgrowth Lines In Vitro

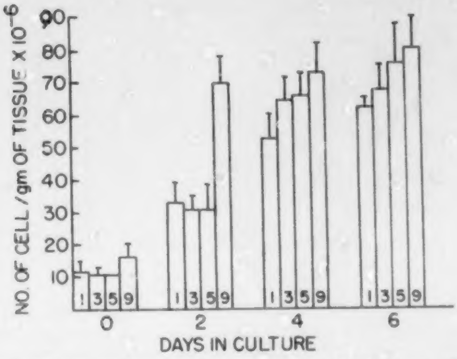
Incorporation of [^{3}H]dThd into the MH tissue was used as a measure of DNA synthesis, and the data are shown in text-figure 1. The general pattern of the kinetics of DNA synthesis in the different MH outgrowth lines was essentially similar during the 6-day incubation period. In each MH outgrowth line, incorporation of [^{3}H]dThd increased steadily to a peak on the fourth day and then declined sharply. The rise of DNA synthesis in MH-1 was rather slow (1.4-fold) during the initial 2 days, although it rose threefold reaching a peak on the fourth day. The increase of DNA synthesis in MH-3 was 2.9-fold at the peak period after 4 days of incubation. In MH-5 DNA synthesis increased at a near linear rate showing a 4.18-fold rise between 0 and 4 days. In MH-9 a 2.3-fold rise occurred between 0 and 2 days, and on the fourth day the total increase reached 2.8-fold. In addition to the variability of the rate of DNA synthesis, the initial zero time values were also variable for the different MH outgrowth lines.

Epithelial Cell Number

The measure of DNA synthesis is likely to provide an average value of the total cell population in the MH tissues. Therefore, a measure of epithelial cell number in the MH outgrowth lines was also obtained after collagenase dissociation of the outgrowth tissues at different times in culture.



TEXT-FIGURE 1.—Kinetics of DNA synthesis in various MH lines in vitro. Gland-free mammary fat pads were incubated in medium with 5 µg insulin/ml, 5 µg prolactin/ml, 1 µg aldosterone/ml, and 5 µg cortisol/ml as described in "Materials and Methods." During the last 1 hr of culture, the fat pads were incubated in medium containing 5 Ci/ml [^{3}H]dThd (20 Ci/mmol; New England Nuclear Corp., Boston, Mass.). At the end of the labeling period, the fat pads were removed, rinsed with cold 0.9% NaCl and blot-dried. For each time point, 15 fat pads containing MH tissue were pooled and defatted with two extractions, each with ethanol:ether (1:1) and ether. The fat pads were then homogenized in cold 5% TCA, and the acid-precipitable material was recovered. After three washes with 5% cold TCA, DNA content and radioactivity were determined in the acid-precipitable material by diphenylamine assay (*28*) and liquid scintillation spectrometry. *Each time point* is a mean of three experiments. *Vertical lines* = positive side of standard deviation.



TEXT-FIGURE 2.—Determination of cell number in MH tissue after incubation in hormonal medium as described in text-fig. 1. At each time interval 20–30 fat pads containing MH tissue were pooled, minced, and incubated with vigorous agitation in Waymouth's medium containing 0.1% collagenase, 0.1% hyaluronidase, and 0.04% DNase at 37°C for 90 min. At the end of the incubation, the reaction mixture was filtered through cheese cloth and then centrifuged at 700×*g* for 5 min. Cells in the pellet were suspended in Waymouth's medium and counted in a hemacytometer. Mammary cells isolated by this procedure yield mostly viable epithelial cells (*14, 15*). *Each bar* is the mean of three experiments. *Vertical lines* = positive side of standard deviation.

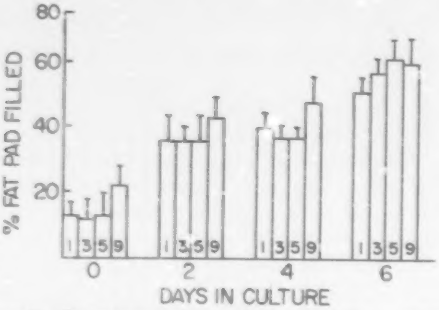
Data in text-figure 2 show that between 0 and 6 days of incubation the number of epithelial cells in the different MH outgrowths increased sixfold to eightfold. While the cell number remained essentially similar among MH-1, MH-3, and MH-5 tissues on different days during the total 6-day incubation, in MH-9 the increase in cell number was markedly greater than others between 0 and 2 days in culture. Subsequently, however, the overall rate of increase (between 2 and 6 days) in MH-9 was lower than the other three MH outgrowths.

Spatial Proliferation of MH Cells in the Fat Pad

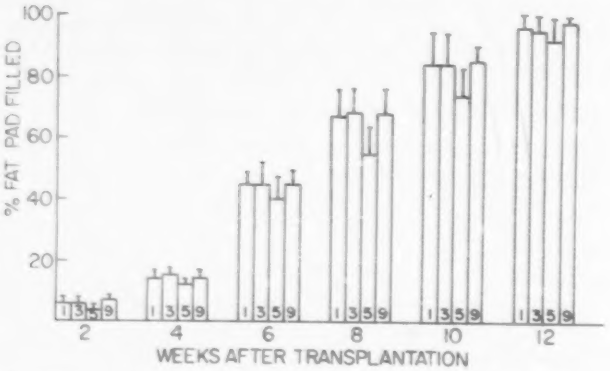
Text-figure 3 shows the data on spatial growth as measured by percentage of the fat pad filled by the outgrowth tissues at different times in vitro. It is clear that during the 6-day culture period each of the MH outgrowth lines grew spatially filling 50–70% of the mammary fat pad. In general, the rate of spatial growth followed a similar pattern.

Figure 1 illustrates the morphology of the MH-9 tissue in the gland-free mammary fat pad in vitro. The growth of the lobulo-alveolar structures at different times of incubation filled nearly 70% of the fat pad in the chemically defined medium, supplemented with insulin, prolactin, aldosterone, and cortisol. Figure 2 illustrates the spatial growth pattern of the MH-5 mixed outgrowth (lobulo-alveolar and ductal) at different times during in vitro incubation in the presence of the same hormone mixture. The characteristic morphology of this mixed outgrowth tissue was maintained even during the in vitro spatial proliferation of the cells. The ductal component of the outgrowth failed to respond to the mammogenic action of the hormone mixture in the medium (*5*).

Proliferation of the MH outgrowth lines was also measured in vivo (text-fig. 4). All four MH outgrowth lines were found to grow filling nearly 100% of the fat pad during a



TEXT-FIGURE 3.—Percent area of fat pad filled by different MH tissues at various times of incubation in vitro. Fat pads containing MH tissues were incubated in the hormone medium as described in text-fig. 1. At each time point fat pads were removed, fixed, and stained with alum carmine. With use of dissecting microscope, the total area of each fat pad and the area occupied by MH tissue were measured (*22*). *Each bar* is mean value of 3-5 fat pads. *No. within bars* indicate different MH tissues. *Vertical lines* = positive side of standard deviation.



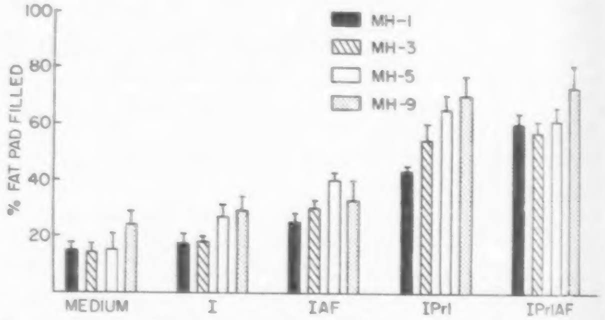
TEXT-FIGURE 4.—Percent area of fat pads filled by different MH tissues during their spatial growth in vivo. Other details are as in text-fig. 3. *Bar* = mean value of four fat pads. *Vertical lines* = positive side of standard deviation.

12-week period after transplantation. The growth rate also showed a similar pattern, although MH-5 appeared to be slightly slower. Figure 3 illustrates the morphology of a lobulo-alveolar MH outgrowth line at different times of its spatial growth in the gland-free mammary fat pad in vivo.

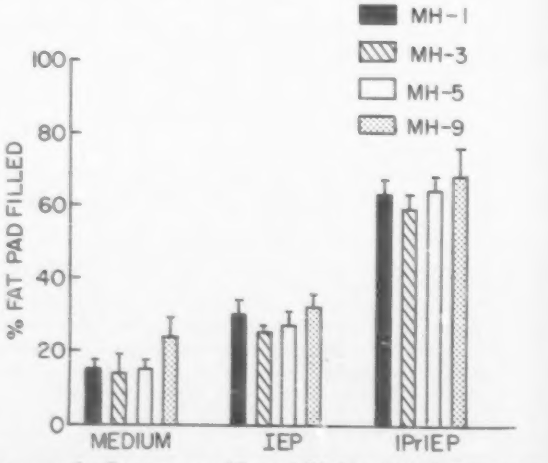
Response of the MH Outgrowth Cell Lines to the Growth-Promoting Action of Hormones

Hormonal influence on growth of the MH outgrowth lines was assessed in vitro by the measurement of the percentage of fat pad filled by the outgrowth tissues after a 6-day incubation period. Responses to different combinations of the hormones insulin, prolactin, aldosterone, cortisol, estrogen, and progesterone were measured. Essentially no growth was observed in the MH tissues after 6 days of incubation in medium without any hormone compared to 0 day (text-fig. 5). Addition of insulin to the medium also failed to promote any noticeable increase in growth in MH-1, MH-3, and MH-9 tissues. However, compared to the medium without any hormone, a 1.8-fold increase in growth was observed in MH-5 tissue in medium with insulin alone. Addition of aldosterone and cortisol to insulin-containing medium failed to increase growth in MH-1, MH-3, and MH-9 tissues. However, MH-5 tissue showed a 2.5-fold increase in growth in medium with insulin and the adrenal steroid hormones. A three- to fourfold increase in growth in all four MH tissues was observed in medium with insulin and prolactin compared to the medium without hormone. Although addition of aldosterone and cortisol to the insulin-prolactin hormone mixture stimulated a noticeably increased growth of MH-1, the growth rate of MH-3, MH-5, and MH-9 remained essentially unaltered in the presence of insulin, prolactin, and adrenal steroid hormones.

Text-figure 6 shows the data on responses of the MH outgrowth lines to the growth stimulatory action of the ovarian steroid hormones in the presence of insulin or insulin plus prolactin. In medium with insulin, estrogen, and progesterone, a twofold increase in growth was evident in MH-1, MH-3, and MH-5; in MH-9 the increase was only 1.3-fold. However, addition of prolactin to medium with insulin, estrogen, and progesterone promoted a marked increase in



TEXT-FIGURE 5.—Area of fat pad (%) filled by the MH tissues in the presence of different combinations of the hormones insulin, prolactin, cortisol, and aldosterone during a 6-day incubation period. Other details are as in text-fig. 1. I=insulin; Prl=prolactin; F=cortisol; A=aldosterone.



TEXT-FIGURE 6.—Percent area of fat pad filled by the MH tissues after a 6-day incubation period in the presence of various combinations of the hormones insulin, prolactin, 0.001 μg 17β-estradiol/ml, and 1 μg progesterone/ml). I=insulin; Prl=prolactin; E=17β-estradiol; P=progesterone. Other details and concentrations of hormones are as in text-fig. 1.

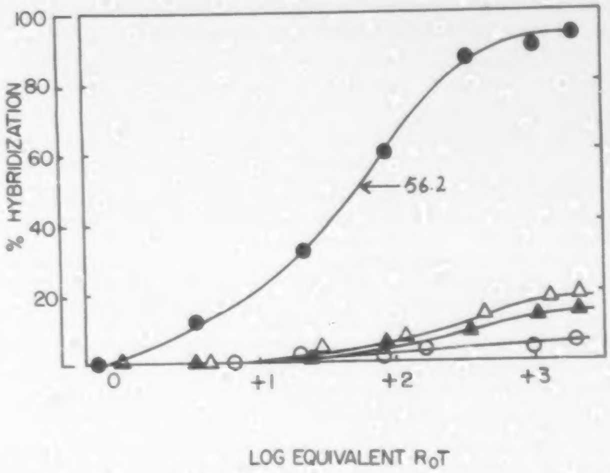
growth in all the MH outgrowth lines, which suggests that the growth potential of the MH tissues is dependent principally on the pituitary polypeptide hormone.

Expression of Functional Differentiation

Functional differentiation was assessed by quantitative measurement of the cellular concentration of mRNAcsn in the MH-1, MH-5, and MH-9 outgrowth lines in vivo. Text-figure 7A shows that in virgin hosts MH-1 and MH-5 tissues failed to accumulate a measurable level of mRNAcsn. However, mRNAcsn was measurable in the same two MH-outgrowth lines carried in lactating hosts, and the $Rot_{1/2}$ values were 74.13 and 234.4 mol·sec·L^{-1} for MH-1 and MH-5, respectively. Quantitative estimates based on these data showed that concentrations of mRNAcsn in total RNA were 0.0044% in MH-1 and 0.0014% in MH-5.

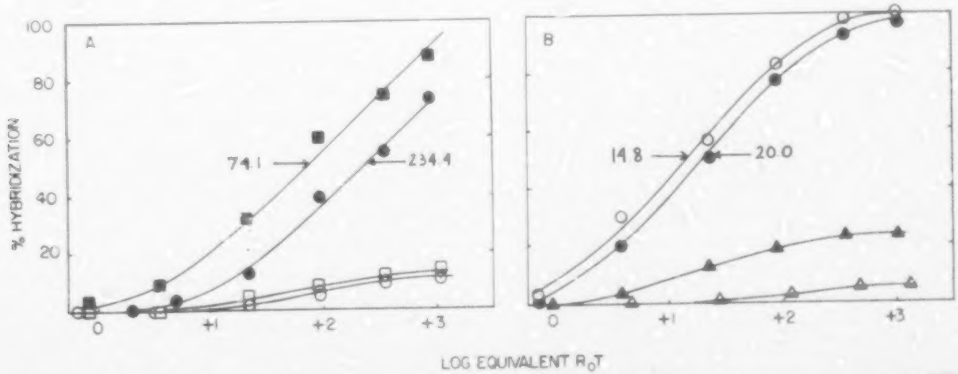
RNA samples obtained from MH-9 outgrowth tissue carried in virgin hosts hybridized to the cDNAcsn probe to completion with a $Rot_{1/2}$ of 14.8 mol·sec·L^{-1} giving a 0.022% mRNAcsn concentration in the total RNA of the tissue (text-fig. 7B). A 100% level of hybridization was also shown by RNA samples from MH-9 cells carried in lactating hosts, and concentration of mRNAcsn sequences in the total RNA was 0.017%. Mammary tumors derived from MH-9 tissue failed to show a measurable level of mRNAcsn in virgin or lactating hosts (text-fig. 7B).

For the purpose of comparison, the HAN-D8 line was included in the present studies. The HAN-D8 is one of the D-series HAN lines which were derived from mammary glands of an old virgin BALB/c mouse chronically hyperstimulated with a pituitary isograft in the renal capsule (*19*). Molecular hybridization data demonstrate that HAN-D8 tissue carried in virgin hosts failed to accumulate a measurable level of mRNAcsn sequences (text-fig. 8). However, RNA from HAN-D8 cells carried in lactating hosts reached a near 100% hybridization with a $Rot_{1/2}$ of 56.2 mol·sec·L^{-1}, reflecting a 0.006% mRNAcsn level in the total RNA. Mammary tumors obtained from HAN-D8 (text-fig. 8) line failed to show a measurable level of mRNAcsn in virgin hosts as well as in lactating hosts.



TEXT FIGURE 8.—Hybridization kinetics of the cDNAcsn probe to total RNA from HAN-D8 tissue and its tumors. ○, HAN in virgin host; ●, HAN in lactating host; △, tumor in virgin host; ▲, tumor in lactating host. *Arrow* indicates $Rot_{1/2}$ value. Tumors in virgin hosts appeared 15 wk after transplantation. For tumors in lactating hosts *see* "Materials and Methods."

To determine the level of expression of the casein gene in the MH and HAN-D8 tissues in virgin and/or lactating hosts, we compared the concentration of mRNAcsn in these preneoplastic tissues to that observed in the normal mammary glands. Accordingly, mRNAcsn concentrations in the normal mammary glands (second thoracic glands) of the host animals were determined by the molecular hybridization assays, and the data are shown in table 2. Whereas no mRNAcsn was detectable in the normal mammary glands of virgin hosts even at Rot values of 1,000 mol·sec·L^{-1}, levels of mRNAcsn in normal glands of pregnant and lactating mice were 0.09 and 2.5% of the total RNA mass, respectively. These results are in agreement with earlier findings in the mammary glands of BALB/c mice (*29*). Since the MH outgrowth lines were derived from the mammary glands incubated for 6 days in medium with insulin, prolactin, aldosterone, and cortisol, mRNAcsn levels in the glands incubated in medium containing the same hormones were also determined. Consistent with our earlier finding (*30*),



TEXT-FIGURE 7.—Hybridization kinetics of cDNAcsn probe to total RNA from the different MH lines and mammary tumors. A) MH-1: □, virgin host; ■, lactating host; MH-5: ⊙, virgin host; ●, lactating host; B) MH-9: ⊙, virgin host; ●, lactating host; △, MH-9 tumor in virgin host; ▲, MH-9 tumor in lactating host. *Arrows* indicate the $Rot_{1/2}$ values. Tumors in the MH-9 tissue carried in virgin hosts appeared 15–20 wk after transplantation. For tumors in lactating hosts, *see* "Materials and Methods."

TABLE 2.—*Concentration of mRNAcsn in the normal mammary glands from mice in different conditions*

Condition[a]	$R_0t_{1/2}$	mRNAcsn,[b] %
Virgin	NM	—
14–15th day of pregnancy	3.7	0.09
5th day of lactation	0.13	2.5
In vitro[c]	17.4	0.019

[a] Normal second thoracic glands were used of virgin, pregnant, or lactating hosts carrying MH tissue in the gland-free inguinal mammary fat pads.

[b] Concentration of the mRNAcsn in the total RNA of the mammary glands was determined by cDNA-RNA hybridization as described in "Materials and Methods." $R_0t_{1/2}$ of the purified 15S mRNAcsn was 0.0033 mol·sec·L^{-1}. NM=not measurable.

[c] Second thoracic mammary glands of 3-wk-old BALB/cAnN female mice primed daily with 1 μg estrogen and 1 mg progesterone for 9 days were incubated in medium with insulin, prolactin, aldosterone, and cortisol for 6 days. Concentrations of the hormones were the same as in text-fig. 1.

TABLE 3.—*Levels of mRNAcsn in total RNA from preneoplastic MH outgrowths compared to mRNAcsn levels in normal mammary glands*

Tissue	Host mice	mRNAcsn,[a] %	Normal gland mRNAcsn levels, % of	
			Lactating mice[b]	In vitro[c]
MH-1	Virgin	NM	—	—
	Lactating	0.0044	0.18	23.1
MH-5	Virgin	NM	—	—
	Lactating	0.0014	0.056	7.3
MH-9	Virgin	0.022	0.88	115.7
	Lactating	0.017	0.68	89.5
HAN-D8	Virgin	NM	—	—
	Lactating	0.006	0.24	31.5

[a] Concentrations of the mRNAcsn were derived from the $R_0t_{1/2}$ values shown in text-figs. 7 and 8. NM=not measurable.

[b] Normal lactating mammary glands are the second thoracic mammary glands of MH- or HAN-D8-carrying lactating hosts. For mRNAcsn levels in these glands, see table 2.

[c] Normal mammary glands in vitro were the second thoracic mammary glands incubated in hormone medium as described in footnote *c*, table 2.

mRNAcsn in these glands was 0.019% of the total RNA (table 2).

On the basis of the above results, mRNAcsn concentrations in MH and HAN tissues were analyzed relative to that in the normal mammary glands of the lactating mice and the mammary gland in vitro (table 3). Although MH-1 and MH-5 tissues accumulate mRNAcsn in the lactating hosts, a quantitative analysis of the data (table 3) revealed that concentration of the mRNA in the MH tissues was only 0.056–0.88% of the hosts' own lactating glands. In MH-1 tissue mRNAcsn concentration in virgin hosts was not measurable, and in the lactating animal the level was 0.18% of that in the normal mammary glands of the respective hosts. The concentrations of mRNAcsn in MH-9 carried in virgin and lactating hosts were 0.88 and 0.68% of that present in the normal glands of the lactating hosts. Compared to that of the normal lactating mammary gland, the level of mRNAcsn in the HAN-D8 tissue was also very low (table 3).

The levels of mRNAcsn in MH-1, MH-5, and HAN-D8 tissues were also lower than the mRNAcsn levels found in the mammary glands after 6 days of incubation in insulin, prolactin, aldosterone, and cortisol. However, the mRNAcsn level in MH-9 tissue in virgin as well as in lactating hosts was as high as that in mammary glands in vitro (table 3).

DISCUSSION

In the present study growth potential of the MH outgrowths was measured during their spatial proliferation filling the gland-free mammary fat pads in a chemically defined medium. The ability of the preneoplastic MH outgrowths to faithfully mimic the characteristic morphogenesis in the culture medium provides a unique in vitro model for measurement of their proliferative potential in a controlled environment.

In a medium containing the hormones insulin, prolactin, aldosterone, and cortisol, the MH outgrowths showed a single wave of DNA synthesis rising to a peak on the 4th day and then declining to their respective near-basal level on the 6th day. A similar single wave of DNA synthesis was also found to be associated with a preneoplastic HAN (D1) outgrowth line during its proliferation in the gland-free mammary fat pad in vitro under similar culture conditions (*22*). Thus the kinetics of DNA synthesis in the MH and HAN outgrowths appear to exhibit a similar pattern during morphogenesis in vitro, even though the etiology and the mode of origin of the two populations of transformed cells are different. In contrast, in the normal mammary gland DNA synthesis rises in two waves during 6 days of lobulo-alveolar morphogenesis in vitro in a medium containing the same hormone mixture (*5*). This suggests an alteration of the kinetic pattern of DNA synthesis in the MH and HAN outgrowths during their lobulo-alveolar morphogenesis in vitro. The increase in DNA synthesis in the MH tissues was accompanied by a rise in epithelial cell number, lobulo-alveolar morphogenesis, and spatial growth filling the fat pad in vitro. This finding suggests that although the kinetics of DNA synthesis in the MH outgrowths has been altered, the MH outgrowth tissues maintain the sequential processes normally associated with lobulo-alveolar morphogenesis of the parenchyma within the constraints of the mammary fat pad. Although the overall growth pattern of the four MH outgrowths examined was essentially similar, each outgrowth line maintained its own characteristic rate of growth increase during the 6-day culture period. The variable growth rate of the different MH outgrowths, however, failed to show any correlation with the tumorigenic potential of the different outgrowth lines.

In MH-5 outgrowth the ductal component of the tissue was maintained during its proliferation filling the fat pad, even though the medium contained insulin, prolactin, aldosterone, and cortisol—a hormone mixture known to stimulate lobulo-alveolar differentiation of the ductal parenchyma of the normal gland in vitro (*5*). This finding suggests that the ductal epithelium in the MH-5 outgrowth line is also in a state of transformation at least with respect to its hormone sensitivity.

Endogenous hormonal milieu in virgin mice is not likely to provide the endocrine environment conducive for lobulo-alveolar morphogenesis of the mammary parenchyma, yet the MH outgrowths fill the gland-free mammary fat pads with lobulo-alveolar structures in virgin hosts. This characteristic suggests an escape of the epithelial cells in the MH outgrowths from the normal endocrine regulation on lobulo-alveolar differentiation. A similar escape from normal hormone regulation is also associated with the HAN tissues (*19*). Thus the MH outgrowths are analogous to HAN with respect to the requirement of the growth-promoting hormones in vivo. With regard to hormone sensitivity of the MH outgrowth in vitro, the medium containing prolactin and insulin is capable of promoting maximal development of lobulo-alveolar structures in MH outgrowth tissues filling the fat pad. Addition of the steroid hormones, aldosterone plus cortisol or estrogen plus progesterone, to the medium generally failed to produce any additive effect on the growth of the MH tissues in the presence of prolactin and insulin in the medium; MH-5 outgrowth showed some responses to the steroid hormones. In contrast, presence of the adrenal and/or the ovarian steroid hormones is essential for stimulation of lobulo-alveolar morphogenesis in the normal glands in vitro (*5, 31*). Thus the ability of MH outgrowths to fill the fat pads with lobulo-alveolar outgrowths in the presence of insulin and prolactin strongly indicates an altered sensitivity of the MH tissues to the mammary growth regulatory steroid hormones. This escape of the MH outgrowths from the growth regulatory actions of the adrenal and the ovarian steroid hormones also corresponds to similar altered sensitivity of the HAN tissues to the steroid hormones. HAN outgrowths have been reported to be maintained in adrenoovariectomized hosts treated with prolactin (*32*). Thus the potentially tumorigenic MH tissues from mammary cells transformed in vitro exhibit an altered hormone requirement for their growth potential essentially similar to that of HAN, induced by the mammary tumor virus or carcinogenic chemical (*19*).

Expression of functional differentiation as measured by accumulation of mRNAcsn in MH-1, MH-5, and HAN-D8 outgrowth lines showed an expected pattern of endocrine response. Accumulation of mRNAcsn in these tissues remained suppressed in the endocrine environment of the virgin hosts, and in the lactating hosts mRNAcsn was measurable in the same outgrowth lines, which suggests that the epithelial cells in these MH outgrowths have retained their sensitivity to the lactogenic hormones. Expression of the casein gene in MH-9 outgrowth, however, was measurable, presumably in the absence of the lactogenic hormone stimulation in the virgin hosts. This measurable expression indicates that the casein gene(s) in MH-9 outgrowth has escaped from the modulatory action of the lactogenic hormones prolactin and glucocorticoid. This abnormality was possibly acquired by the mammary cells during the transformation process, initiated apparently, in consequence to interactions between the electrophilic reactants of DMBA and the mammary cell DNA (*7, 8*). Expression of the casein gene in the mammary gland in vitro is dependent on hormone induction (*30*). The mechanisms associated with expression of the casein gene in MH-9 outgrowth in the inadequate endocrine environment of the virgin hosts are intriguing, and future studies are likely to provide some interesting information. Accumulation of mRNAcsn in MH-9 outgrowth, exposed to the lactogenic hormone environment of the nursing mother, may be considered an usual response of the tissue, except that the concentration of the mRNA sequences remains essentially similar to that observed in the same tissue in the virgin host. This then raises the possibility that the cells accumulating the mRNAcsn in virgin and lactating hosts represent the same population.

Another point of interest about the characteristic of casein gene expression observed in the MH outgrowths and HAN-D8 lines concerns concentration of the mRNAcsn accumulated in these tissues. Although mRNAcsn was measurable in these preneoplastic tissues when exposed to the lactogenic endocrine environment of the post-partum animals, concentrations of the mRNAcsn sequences in the different preneoplastic tissues represent only 0.056–0.88% of that observed in the normal lactating mammary glands of the host animals. This reduced level of casein gene expression in the MH and HAN outgrowths may not reflect hormone responses of a micropopulation of normal mammary cells present in the preneoplastic tissue, because normal mammary cells have a finite life expectancy of 9–11 serial transplant generations (*33*). MH outgrowths have been carried in our laboratory through 20–25 transplant generations, and likewise HAN-D8 has been maintained since 1969. Thus the reason for the reduced level of expression of the casein gene in the MH and HAN tissues remains unclear at this time. However, the reduced level of mRNAcsn accumulation in the MH outgrowths may reflect expression of the casein gene in micropopulation of transformed cells which have retained their ability to respond to the modulatory action of the lactogenic hormones. Partial inactivation and/or loss of the specific hormone receptors may also cause a reduced sensitivity of the cells to the lactogenic hormones. A loss of certain steroid hormone receptors in some HAN lines has been reported (*34*). Studies in our laboratory have also shown a depletion of glucocorticoid receptor in the MH outgrowths (Majumder P, Banerjee MR: Unpublished observation).

Mammary tumors obtained from the MH and HAN-D8 outgrowths in general failed to show a detectable level of mRNAcsn, regardless of the endocrine status of the host. This finding indicates a virtual absence of casein gene expression in the neoplastic mammary tissue of the mouse. Thus it appears that during the multistep transformation process the mammary cells progressively lose their ability to respond to the hormones regulating expression of functional differentiation. A similar trend of reduced functional activity also has been reported to be associated with liver carcinogenesis in rats. In normal liver albumin mRNA constitutes 10% of the total poly(A) RNA, but its concentration is reduced significantly in Morris hepatomas (*35*).

Rat mammary tumor cell line R3230AC as well as DMBA-induced rat mammary tumors are mostly nonresponsive to prolactin and/or estrogen stimulation of mRNAcsn accumulation (*36, 37*). Consistent with the present results, several hormone- or DMBA-induced HAN lines of BALB/c mice have been reported to be only moderately responsive to exogenous hormone stimulation (prolactin and dexamethasone), and mammary tumors derived from these preneoplastic tissues in general are nonresponsive (*38*).

In conclusion, results of the present studies provide further evidence that altered responses of the MH outgrowths to the hormones that regulate growth and functional differentiation of the mammary cells are similar to those of the HAN tissues found in mouse mammary glands. Thus the preneoplastic MH outgrowths derived from mouse mammary cells transformed in organ culture are analogous to the HAN tissues derived from transformed cells in mouse mammary gland in vivo.

Effect of Immunomodulation on the Fate of Tumor Cells in the Central Nervous System and Systemic Organs of Mice. Distribution of [^{125}I]5-Iodo-2′-deoxyuridine-Labeled KHT Tumor Cells After Left Intracardial Injection[1,2]

Frances K. Conley[3,4,5]

ABSTRACT—The effect of systemic immunomodulation on tumor cell arrest and retention in the central nervous system was studied by following radioactively labeled tumor cells. KHT mouse sarcoma tumor cells were labeled in vitro with [^{125}I]IdUrd, and 1×10^6 tumor cells were injected into the left side of the hearts of syngeneic C3H mice. Experimental groups consisted of untreated normal mice, mice pretreated iv with *Corynebacterium parvum*, and mice chronically infected with *Toxoplasma gondii*; in this model both groups of immunomodulated mice are protected from developing systemic metastatic tumor, but only *Toxoplasma*-infected mice have protection against metastatic brain tumor. At time intervals from 1 to 96 hours, groups of mice from each experimental group were killed, and the brain and other organs were monitored for radioactivity to determine the number of viable tumor cells that had been present at the time of death. Normal mice demonstrated significant retention of tumor cells in the brain and kidneys plus adrenals at 96 hours. By contrast, in both groups of immunomodulated mice tumor cells were rapidly eliminated from systemic organs, but tumor cells were significantly retained in the central nervous system even at 96 hours after tumor cell injections. The results indicated that generalized immunomodulation had more effect in elimination of tumor cells from systemic organs than from the brain and that the elimination of tumor cells from the brain in *Toxoplasma*-infected mice was a delayed phenomenon.—JNCI 1982; 69:465–473.

The ultimate control of cancer will depend on the development of therapeutic mechanisms that will successfully stop the metastatic spread of cancer cells. In attempts to define the biologic behavior of the arrest and trapping of tumor cells that have been released into the circulation, many investigators have followed the fate of radioactively labeled, iv injected tumor cells. [^{125}I]IdUrd has become the radioactive label of choice for these studies because it is incorporated into the DNA of viable, proliferating cells and is rapidly eliminated upon cell death with negligible reutilization (*1–3*). Following iv injection of cells, the lung is the initial recipient organ of the tumor cell bolus and thus is the organ studied most extensively. Several immunologic and mechanical factors, such as immune status of the host (*4–6*), immunogenicity and viability of the tumor cells injected (*7–10*), deformability of tumor cells (*11–13*), anticoagulation status of the host (*7*), or thromboplastic activity of the tumor (*14*), can influence the arrest and retention pattern of tumor cells in the lung. Tumor cell traffic to other organs following passage through the pulmonary vasculature has also been explored (*15, 16*).

Because in human oncology the brain is a frequent site of symptomatic metastatic disease, we have been interested in defining arrest and retention patterns of tumor cells in the CNS. In humans most tumor emboli reach the brain from an arterial source (*17*), and we have developed a metastatic brain tumor model in mice in which the tumor cells are injected into the left side of the heart and thus are initially distributed to the brain by arteries (*18*). Tumor also develops in the kidneys, adrenals, and ovaries. Using this model in prior work, we explored the ability of two agents that cause systemic immunomodulation to affect the ultimate development of metastatic brain tumor, and we were able to document that the treatment with *Corynebacterium parvum* eliminated systemic tumor but had no effect whatever on brain tumor metastasis, whereas chronic infection with *Toxoplasma gondii* was able to eliminate both systemic and CNS tumor (*19*). In the present study we have followed the fate of [^{125}I]IdUrd-labeled tumor cells following ic injections in normal mice, *C. parvum*-treated mice, and *Toxoplasma*-infected mice to define the effect of immunomodulation on the arrest and retention pattern of tumor cells in the brain and to compare this pattern of tumor cell traffic in the CNS with that in systemic organs.

MATERIALS AND METHODS

Mice.—C3H/HeN/MTV-negative syngeneic female mice were obtained from Simonsen Laboratories, Gilroy, Calif., and were 2–4 months old at the beginning of the experiments. For each experiment all mice were age matched. Starting 3–4 days before injection of labeled tumor cells, the drinking water was supplemented with 0.1% sodium iodide

for prevention of radioactive iodine accumulation by the thyroid gland.

Infection with T. gondii.—To establish a chronic infection with *Toxoplasma,* we gave mice inoculations ip of 1×10^5 of the C56 strain of *T. gondii* in the tachyzoite state and treated them with sulfadiazine for 3 weeks as previously described (*20*). Mice received tumor cell injections 3–8 weeks after termination of sulfadiazine therapy.

Treatment with C. parvum.—A suspension of killed *C. parvum* (lot #CA771/B; 7 mg/ml dry wt) was obtained from Burroughs-Wellcome Ltd., Beckenham, England. *C. parvum* was administered iv 3 days before tumor cell inoculations at a concentration of 700 μg/mouse in a total volume of 0.2 ml of normal saline. Prior work from our laboratory had determined that this dose and schedule of *C. parvum* administration protected mice from developing systemic metastatic tumor but that it did not provide protection against metastatic tumor to the brain (*19*).

Tumor.—Cell lines of the KHT mouse sarcoma, a tumor that arose spontaneously in a C3H mouse, were grown in Eagle's minimum essential medium (Grand Island Biological Co., Grand Island, N.Y.) and supplemented with 15% fetal calf serum, l-glutamine, sodium bicarbonate, and kanamycin (1 g/100 ml). Cell cultures were incubated at 37°C in a humidified atmosphere containing 5% CO_2. All studies were done with cell populations in the exponential growth phase.

Preparation of cells for study of cell arrest and dissemination in vivo.—KHT cells were labeled with $[^{125}I]$IdUrd (Amersham Corp., Arlington Heights, Ill.) at a labeling dose of either 0.05 or 0.02 μCi/ml of medium for 48 hours. After incubation the cells were harvested and washed three times for removal of nonbound isotope. Cells were resuspended in Hanks' balanced salt solution with kanamycin (1 g/100 ml), checked for viability by exclusion of trypan blue (90–95% viable), and diluted to yield an inoculum dose of 1×10^5 viable cells per 0.2 ml of cell suspension. To determine the percentage of cell labeling, we made cytocentrifuge preparations from a 1:10 dilution of the inoculum dose and autoradiographed them. Representative inoculum doses were monitored in a well-type scintillation counter (Searle gamma counter, model #1185; G. D. Searle & Co., Des Plaines, Ill. 60018). Triplicate samples were collected both before and after animal injections, and these aliquots of 1×10^5 cells yielded similar counts in each individual experiment.

Inoculation and evaluation of labeled tumor cells.—Mice received 0.2 ml of labeled tumor cells by iv injection into a lateral tail vein (normal mice only) or by direct left ic injection (normal and *Toxoplasma*-infected and *C. parvum*-treated mice.) At time periods from 1 to 96 hours after injection, 5 mice from each experimental group were rapidly exsanguinated; blood, brain, lungs, spleen, and kidneys plus adrenals (in all experiments both kidneys and both adrenals from each mouse were removed and counted together) were collected from each animal. In some experiments the liver was also included. Solid organs were placed in individual vials containing FAA fixative (10 ml of 37–40% formaldehyde, 90 ml of 80% ethyl alcohol, 5 ml of glacial acetic acid). The fixative was changed every 24 hours for 3 days for removal of the acid-soluble fraction of ^{125}I (*21, 22*) released from the DNA of dead tumor cells (*23*). We had previously determined that the FAA fixative was as effective as 70% ethyl alcohol in eluting the acid-soluble fraction and that it was much superior to 70% ethyl alcohol for tissue preservation for subsequent histologic examination and autoradiography. Blood and solid organs were monitored in a well-type scintillation counter, and the number of viable tumor cells present in each organ was determined from the radioactivity counts. The number of tumor cells in each organ was expressed as a percentage of the total injected dose. Experiments in which tumor cells were injected ic were repeated six times, but not all time intervals were sampled in every experiment. Because the organ counts changed in the same direction at the same time intervals in all experiments, the results were pooled. Statistical evaluations for significance were done by Student's *t*-test.

Evaluation of distribution and arrest of heat-killed tumor cells.—Labeled tumor cells were killed by being heated to 70°C for 10 minutes, and 1×10^5 cells in 0.2 ml media plus antibiotic were injected ic into normal mice. For each time period (1, 2, 4, 24, and 48 hr) 5 mice were rapidly exsanguinated, and blood and organs were collected and processed as above.

Preparation of material for histologic examination.—After counting the total radioactivity of each individual organ, we processed the organs for light microscopy. We cut representative paraffin-embedded tissue sections at 5 μm, autoradiographed them using NTB 2 emulsion (Eastman Kodak Co., Rochester, N.Y.) at an exposure time of 3 weeks, and stained them with H & E.

RESULTS

Cell Labeling and Evaluation of Metastatic Potential

In preliminary experiments we used three concentrations of $[^{125}I]$IdUrd for labeling tumor cells in vitro. Almost 100% of KHT cells incubated for 24 hours with 0.5 μCi $[^{125}I]$-IdUrd/ml medium were heavily labeled. Tumor cells labeled with 0.05 μCi $[^{125}I]$IdUrd/ml or 0.02 μCi $[^{125}I]$IdUrd/ml for 24 hours demonstrated 70–75% labeling; if the incubation time was extended to 48 hours at these concentrations, the percentage labeling improved to 90–95% and the amount of label per cell was increased.

We assessed metastatic capability by giving normal mice ic injections of either 1×10^5 labeled tumor cells or 1×10^5 nonlabeled tumor cells and by following the animals to time of death. All mice were autopsied and the gross numbers of parenchymal brain tumor metastases visible on the surface of the brain were counted with a dissecting microscope. [A proportionality exists between the dose of tumor cells injected ic and the number of visible metastatic tumor deposits that can be counted on the surface of the brain at the time of death (Conley FK: Unpublished data).] When a concentration of 0.5 μCi $[^{125}I]$IdUrd/ml was used as a labeling dose, mice receiving injections of labeled cells died an average of 4 days later than did mice receiving the same dose of unlabeled tumor cells and had fewer tumor nodules in the brain, indicating that this concentration of radioactive label was toxic to the tumor cells. Mice receiving KHT cells labeled with $[^{125}I]$IdUrd at concentrations of 0.05 or 0.02

μCi/ml and an incubation time of 48 hours died at the same time as did mice receiving nonlabeled cells; the average and median counts of brain tumor metastases were identical between the 2 groups. At the lowest concentration of [^{125}I]-IdUrd, 0.02 μCi/ml, the counts per cell ranged from 0.16 to 0.36 in individual experiments, providing sufficient radioactivity to follow cells adequately after injection; this labeling concentration was used in all subsequent experiments.

Fate and Distribution of KHT Tumor Cells Following Injection in Normal Mice

Following iv injection of KHT sarcoma, the lung is the only organ to consistently develop tumor nodules, and at the dose of 1×10^5 cells the tumor in the lungs is confluent at the time of death. The organ distribution of labeled KHT cells from a single experiment in normal mice is shown in table 1 and text-figure 1. At 1 hour 81% of the total injected dose was in the lungs. By 8 hours this figure had dropped to 33%; at 48 hours 6.3% of the original inoculum of tumor cells still resided in the lungs. Very small numbers of tumor cells were detectable in the spleens and kidneys plus adrenals for the first 8 hours, and none were detectable by 24 hours after tumor cell injections. Tumor cells were not detectable in the brain at any time interval. From 1 to 8 hours after injections, radioactivity counts in the blood rose from 2.3 to 3.1%, but radioactivity was absent from the blood at 48 hours.

Dissemination and Arrest of Labeled Tumor Cells Following Left ic Injection in Normal Mice

A marked discrepancy of radioactivity counts between lungs and brain in individual animals made it easy for us to determine when the tumor cell bolus had not been injected into the left side of the heart. Any animal that had received a "missed injection" was eliminated from all tabulation of results. Table 2 and text-figures 2–5 give composite results from multiple experiments of the distribution of labeled tumor cells in various organs at time intervals following left ic injection. Unlike the distribution of tumor cells following iv injection, appreciable numbers of arterially disseminated cells reached the brain and kidneys plus adrenals, and in normal mice a constant number of tumor cells tended to remain in these organs over the first 8 hours. By 96 hours 1% of the total injected dose was still detectable in the brain, and 2% of the total injected dose was still present in the kidneys plus adrenals. Radioactivity counts in the blood and spleen were stable over the first 8 hours, but both fell to 0.1% by 48 hours post injection. The number of tumor cells arresting in the lungs increased over the first 4 hours, then gradually declined so that by 96 hours only 0.2% of the total injected dose remained. At no time interval did greater numbers of tumor cells exist in the lungs than in the brain.

Dissemination and Arrest of Labeled Tumor Cells Following Left ic Injection in Immunomodulated Mice

The dissemination of labeled tumor cells in various organs in *Toxoplasma*-infected mice and *C. parvum*-treated mice are presented in tables 3 and 4 and text-figures 2–5, all of which represent composite data from multiple experiments. When compared to normal mice, both groups of immunomodulated mice demonstrated a different pattern of arrest of tumor cells between systemic organs and the brain. In *C. parvum*-treated mice 10% of the total injected dose of tumor cells was present in the brain at 1 hour. This percentage dropped over the next hour to 6.5% but then remained relatively constant for the first 8 hours after ic injection. Similarly, in the *Toxoplasma*-infected mice, there was a drop in the num-

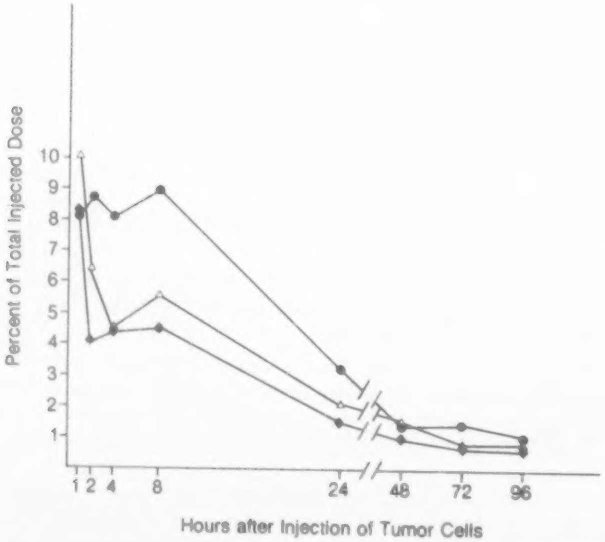
ber of tumor cells in the brain from 1 to 2 hours (8.3–4.1%), but then there was a tendency for a constant number of tumor cells to remain for the first 8 hours. From 8 to 48 hours after injections in both groups of immunomodulated mice, the number of tumor cells in the brain progressively declined but then stabilized, so that even at 96 hours after injections detectable levels of tumor cells remained in the brain. In the systemic organs, by contrast, at time intervals after 1 hour in both groups of immunomodulated mice, there was a rapid progressive decline in the number of tumor cells present in the lungs and kidneys plus adrenals; by 48 hours after tumor cell injections, cells were undetectable in these organs. We noted a small progressive increase in radioactivity counts in the blood over the first 8 hours and then a rapid decline to undetectable levels by 48 hours. When compared to normal mice, immunomodulated mice had increased numbers of tumor cells lodged in the spleens; but no significant peak of splenic uptake of tumor cells was seen in either group at any time period, and by 48 hours the number of tumor cells in the spleen was the same in normal and immunomodulated mice.

Dissemination and Arrest of Labeled Heat-Killed Tumor Cells After ic Injection in Normal Mice

The results of this single experiment are shown in table 5. When dead tumor cells were injected intra-arterially, these cells were eliminated extremely rapidly from systemic organs over the first 2 hours. Not as many dead tumor cells initially lodged in the brain as did live tumor cells, and a progressive gradual decline in cell numbers was seen over the first 4 hours; negligible numbers of tumor cells remained in the brain by 24 hours. The only organ to maintain detectable radioactivity counts at 24 hours was the spleen, but no peak of splenic sequestration was encountered at the time intervals sampled.

Histologic Examination and Autoradiography

Labeled tumor cells were readily visualized in brain, lungs, and kidney plus adrenals. By light microscopy it was often impossible to determine with certainty the intravascular or extravascular location of a given labeled tumor cell.



TEXT-FIGURE 2.—Percent of [^{125}I]IdUrd-labeled KHT tumor cells in the brains of normal mice, *Toxoplasma*-infected mice, and *C. parvum*-treated mice following left ic injection of 1×10^5 tumor cells. Normal, ●; *Toxoplasma* infected, ◆; *C. parvum* treated, △.

TEXT-FIGURE 5.—Percent of [^{125}I]IdUrd-labeled KHT tumor cells in the kidneys plus adrenals of normal mice, *Toxoplasma*-infected mice, and *C. parvum*-treated mice after left ic injection of 1×10^5 tumor cells. Normal, ●; *Toxoplasma* infected, ◆, *C. parvum* treated, △.

In the brain, tumor cells were randomly distributed and initially appeared to be trapped in capillaries (fig. 1), but even at 96 hours after tumor cell injections the occasional labeled cell was found still in what appeared to be an intravascular location. Forty-eight hours after injections, however, more labeled tumor cells appeared to be parenchymal than intracapillary. Tumor cells in the brains of normal or *C. parvum*-treated mice elicited no obvious parenchymal reaction (fig. 2). By contrast, tumor cells in the brains of *Toxoplasma*-infected mice very frequently, but not

always, resided in close proximity to collections of small mononuclear cells (figs. 3, 4).

DISCUSSION

This study demonstrated that with the KHT tumor a considerable number of tumor cells reach the brain but only after arterial dissemination and that systemic immunomodulation had a much greater influence on the arrest and retention of tumor cells in systemic organs than in the brain. Following ic injections a tumor nodule develops at the injection site in the heart and uniformly tumor deposits are present in the brain, kidneys plus adrenals, and ovaries. The occasional mouse will also develop 1 or 2 tumor nodules in the lungs. The number of tumor cells arrested and retained in the organs of normal mice in this study would predict this pattern of ultimate tumor growth. The brain and kidneys plus adrenals were the organs that collected the largest percentage of labeled tumor cells, and in normal mice at both of these sites there was significant retention of viable tumor cells at 96 hours following the tumor cell injections. Whereas some tumor cells initially did arrest in the lungs, a subsequent steady decline was seen in the number of viable cells such that by 96 hours only 0.2% of the total injected dose remained; the lung is not a primary target organ of KHT tumor growth after ic injection of tumor cell suspensions as it is after iv injections.

Previous work by our laboratory (*9*) had documented that both *C. parvum*-treated mice and mice chronically infected with *Toxoplasma* had excellent protection against the development of systemic KHT tumor following ic injection of tumor cells. The pattern of tumor cell arrest in the lungs and the kidneys plus adrenals was very different in both groups of immunomodulated mice when compared to that in normal mice. With immunomodulation there was a rapid loss of viable tumor cells from these systemic organ sites over the first 4 hours after injections, followed by a progressive but less rapid loss such that tumor cells were undetectable in the lungs at 48 hours and not detectable in the kidneys plus adrenals at 72 hours. KHT tumor rarely develops in these organs in *C. parvum*-treated mice or *Toxoplasma*-infected mice. We can only speculate as to mechanisms responsible for the observed decrease in tumor cell numbers and ultimate tumor growth in our immunologically modified animals. In a study involving immunologic manipulation, Fidler et al. (*4*) found that after iv injections of tumor cells mice with specific immunity to the tumor had increased initial arrest of tumor cells in the lungs whereas thymectomized, irradiated adult mice did not but that both groups of mice resisted the ultimate development of metastatic lung nodules. They (*4*) concluded that immunomodulation could influence the initial arrest of tumor cells in the lungs but not the amount of final metastatic tumor growth. Similar to our results where nonspecific immune mechanisms were explored, Glaves (*24*) reported that, compared to untreated mice, mice pretreated with endotoxin rapidly cleared iv injected tumor cells from the lungs, demonstrated a concomitant short-term increase of tumor cells trapped by the liver, and developed fewer ultimate lung tumor nodules. Close comparison of results from these studies and ours, however, is difficult because of differences in experimental design; e.g., the mice used by Glaves, treated or not, were all tumor-bearing.

Recent work by other investigators (*25–33*) suggested an important role for the NK cell in the elimination of circulating metastatic tumor cells; the curves we obtained of tumor cell arrest and retention following ic injection are consistent with intracirculatory NK cell activity in our immunomodulated mice. *C. parvum* treatment produces increased numbers of NK cells (*29*), and recently Hauser et al. (*34*) demonstrated that both acute and chronic *Toxoplasma* infection in mice is associated with increased NK cell activity; so both groups of our immunomodulated mice should have had more NK cells than our normal, control mice, many of which were old enough at the time of experiments to have lost much of their natural NK cell activity, which probably peaks at 5–10 weeks of age in the mouse (*33*). Electron microscopy has demonstrated that KHT tumor cells, having escaped intracirculatory destruction, can be within the lung parenchyma by 6 hours after iv injection (*7*). Beyond 8 hours in our study, the curves of viable tumor cell loss in normal mice following ic tumor cell injection and in both groups of immunomodulated mice were roughly parallel, indicating perhaps that continued destruction of tumor cells trapped in the organs themselves did not differ between normal and immunomodulated mice. Thus the fact that immunomodulated mice develop very little systemic tumor may be on the basis of early elimination of sheer numbers of tumor cells after their injection into the circulation (i.e., by NK cells) rather than on the basis of nonspecific immunologic mechanisms acting within the parenchyma of a target organ. A similar explanation of results was used by Brown and Parker (*7*) who studied the effect of immunomodulation on iv injected radiolabeled KHT tumor cells in the lungs and by Bishop and Donald (*35*) working with 2 other murine tumor lines; their explanations would agree also with the conclusions of Fidler et al. (*4*). Also, possibly the slow loss of viable tumor cells from systemic organs represents delayed, nonimmunologically mediated death of cells damaged by circulation through the pulmonary vasculature, as suggested by Weiss (*15*).

In light of the above possibilities, the effect of immunomodulation on the arrest and trapping of tumor cells in the brain holds interest for investigators. Similar to observations in the systemic organs is the observation of an immediate decline in the number of viable tumor cells in the brains of both groups of immunomodulated mice over the first 2 hours after ic tumor cell injections, with the number of tumor cells remaining fairly constant for the next 6 hours (8 hr after injections). In the normal mice an immediate rapid loss of cells was not observed, and the number of tumor cells in the brain remained at a constant level approximately twice that of the immunomodulated mice for the first 8 hours. Subsequently, in all 3 groups of mice a steady, gradual decline occurred in the number of viable cells until 48 hours after injection, when the number of tumor cells remaining again became constant at approximately the same number of cells in the brains of both normal and immunomodulated mice. A decline in the number of viable cells to undetectable levels in the brains of immunomodulated mice did not occur as had been observed in the systemic organs, and the brain was the only organ to sequester and hold a constant number of viable tumor cells regardless of the immunologic status of the animal. (Killed tumor cells were eliminated from the brain very rapidly.) This dichotomy suggests that in systemic organs nonspecific immune mechanisms, possibly via the activated macrophage (*36-41*), are present and can inactivate or kill tumor cells in the parenchyma of a particular organ but that the brain does not develop similar antineoplastic ability as a result of systemic immunomodulation at least for the first 96 hours following tumor cell injections.

However, it is known that *Toxoplasma*-infected mice resist the development and growth of both directly implanted and metastatic tumor to the brain, whereas *C. parvum*-treated mice do not (*19, 42, 43*). Only minute quantities of *C. parvum* reach the brain when it is given iv (*44, 45*), and the brains of our *C. parvum*-treated mice showed no histologic changes. In our previous work we had documented a remarkable increase in a base-line inflammatory cell reaction in the brains of *Toxoplasma*-infected mice following ic injection of KHT tumor cells and had postulated that this inflammatory response was responsible for elimination of metastatic tumor. The base-line inflammatory response is present in the brain as a direct result of *Toxoplasma* organisms invading the brain parenchyma and leaving a long-standing antigenic stimulus (*46*). Our autoradiographic, histologic studies demonstrated that labeled tumor cells in the brains of *Toxoplasma*-infected mice were surrounded by small mononuclear cells much more frequently than were labeled tumor cells in the brains of normal mice or *C. parvum*-treated mice. Whether these observations by light microscopy have significance remains speculative, but our results indicate that measurable tumor cell destruction in the brain induced by *Toxoplasma* infection probably did not occur within the first 96 hours after tumor cell injections. Unfortunately, the technique of following labeled intra-arterially injected tumor cells was not sufficiently sensitive to allow us accurately to follow tumor cell elimination for time periods beyond 96 hours, so we do not yet know the time course of tumor cell stasis or lysis in the brain of a *Toxoplasma*-infected mouse. Our study does suggest, however, that in the brain, and possibly in other organs, little hope exists that nonspecific immunologic activity that is induced after a tumor has disseminated will be effective against metastatic tumor growth unless mechanisms are developed that will directly stimulate a parenchymal immune response in a particular organ. A population of NK cells may be essential for reduction of the viable tumor burden detaching and entering the circulation, but there must be subsequent local specific and nonspecific immunologic mechanisms that act to eliminate a small number of viable tumor cells remaining in an organ. The brain apparently does not develop parenchymal nonspecific immunologic reactivity as a result of systemic immunomodulation, unless, as with *Toxoplasma* infection, the stimulating agent actually reaches the brain. The observed increased number of patients who develop brain metastases after successful treatment of the primary tumor and systemic metastatic disease (*17, 47, 48*) may be the result not only of chemotherapeutic agents failing to reach the brain but also of a present lack of a therapeutic mechanism which would result in production of local immunologic reactivity in the CNS.

Role of Prostaglandin E_1 and Copper in Angiogenesis[1,2]

Marina Ziche,[3,4] **John Jones,**[5] *and* **Pietro M. Gullino**[3,6,7]

ABSTRACT—The interstitial fluid of MTW9A and Walker carcinomas and their ethanol extract induced strong angiogenic response in the rabbit (New Zealand White) corneal test. The fluid collected in vivo was rich in E-type prostaglandins, and prostaglandin E_1 (PGE_1) in particular was strongly angiogenic at the lowest dose as compared with the angiogenic responses of prostaglandins E_2, I_2, and $F_{2\alpha}$. Neoplastic fibroblasts also induced a strong angiogenic response, but in indomethacin-treated rabbits neovascularization failed to occur. Copper was concentrated in the cornea during PGE_1-induced neovascularization, and copper-deficient rabbits were unable to mount an angiogenic response in the corneal test. Ceruloplasmin, the copper carrier of plasma, was found to be angiogenic at high doses. In indomethacin-treated rabbits, however, ceruloplasmin at the same high doses failed to induce angiogenesis. The experiments are interpreted to indicate that angiogenesis is the end result of a sequence of events, two of which are PGE_1 production and copper mobilization in the tissue where neovascularization occurs.—JNCI 1982; 69:475–482.

New formation of vessels is an event common to a variety of physiologic and pathologic processes. Tumor growth in particular depends on new formation of a large number of vessels, and experiments have been performed which indicate that the lack of angiogenesis prevents or arrests tumor growth (*1–3*). Recent evidence suggests also that acquisition of angiogenic capacity by tissues normally deprived of this capacity may indicate a high risk of neoplastic transformation (*4–6*).

The morphogenesis of a capillary involves a sequence of events usually described as mobilization of the endothelium in a controlled direction, cellular proliferation, canalization of a solid bud, and production of a periendothelial stroma. The conditions necessary to trigger this sequence of events are poorly understood. As a contribution to the understanding of the mechanism of angiogenesis, experiments have been conducted with the use of the rabbit corneal test. The results reported here indicate that production of PGE_1 and increased concentration of copper in the cornea to be invaded by capillaries are two events that occur during the angiogenesis process.

MATERIALS AND METHODS

Rabbits.—Male or female New Zealand White rabbits, 2–3 kg in body weight, were utilized for the angiogenesis test. The animals were kept in an air-filtered room with a 12-hour dark–light cycle. The normal diet was Purina Rabbit Chow 5321 (Ralston Purina Co., St. Louis, Mo.) and tap water ad libitum. The copper-deficient diet was #901409 (Nutritional Biochemicals Corp., Cleveland, Ohio) and deionized water.

Rabbits fed the copper-deficient diet reduced their total food consumption about 25%, and the weight gain at the end of 1 month averaged 35% less than that for rabbits receiving a normal diet. This diet did not severely impair the animals' health; upon return to a normal diet, the rabbits regained weight promptly and in about 3 weeks their weight matched the weight of rabbits on a normal diet. After the animals were on the deficient diet for 4 weeks, the copper content of their sera was usually reduced to 50% of the initial values. In about 20% of the rabbits, however, the serum copper level never decreased below 70–80% of the initial values, and these animals were not used in the experiments. The copper concentration in serum was utilized so that we could ascertain that copper deficiency was established and could select rabbits with comparable depression of serum copper concentration to ensure uniformity of response. To enhance the removal of available copper 6 days before and during the experiment, we gave each deficient rabbit three 20-mg doses orally of D-penicillamine (#4875; Sigma Chemical Co., St. Louis, Mo.) in deionized water at about 9 a.m., noon, and 4 p.m.

Surgical procedures were performed under sodium Nembutal anesthesia (30 mg/kg, #8612; Abbott Laboratories, North Chicago, Ill). In addition, after the eye was proptosed, a few drops of 0.5% tetracaine hydrochloride were placed on the cornea. After surgery, the observation of the implant with the slit-lamp stereomicroscope did not require anesthesia.

Rabbits undergoing indomethacin treatment were kept on a normal diet and received orally three 25-mg capsules of Indocin (#3316; Wholesale Drug Co., Landover, Md.) each day at about 9 a.m., noon, and 4 p.m. Treatment was started 6 days before corneal implant and continued during the entire observation period. In addition, after the corneal implant was completed, a drop of Vaseline containing about 20 mg of indomethacin was placed on the eye bulb three times a day for enhancement of the anti-PGE_1 effect.

Rats.—MTW9A carcinomas (*7*) transplanted subcutaneously in WF female rats, 2–3 months old, were utilized for the TIF sampling. The technique has been previously de-

scribed in detail (*8*). A chamber about 13 mm in diameter, with walls constituted by Millipore filters (0.45-μm pore size) and bearing a PE50 catheter (Clay, Adams Inc., Parsippany, N.J.), was inserted in a pouch of the subcutaneous tissue of the interscapular region. About 200 mg of tumor slurry was injected into the subcutaneous pouch around the Millipore chamber. Within 5–6 days a 3- to 4-g tumor had incorporated the chamber. The neoplastic cells grew against the Millipore filter but did not penetrate the chamber's cavity, whereas the fluid surrounding the neoplastic cells did penetrate and was sampled via the catheter. The fluid volume was about 150 μl for each chamber, and the color was like that of serum. As the tumor grew larger, the fluid became hemorrhagic and was not utilized.

Walker carcinoma (*9*) transplanted subcutaneously in noninbred Sprague-Dawley females, 2–3 months old, was also used in several determinations of TIF angiogenic capacity. No appreciable difference was found between the two fluids.

Cell cultures.—Fibroblasts from the subcutaneous tissue of BALB/c male mice 6 weeks old were utilized for induction of angiogenesis. The cells were removed from the donor by injection of 3 ml of a 0.5% bacterial collagenase (#4196, code CLS; Worthington Biochemical Corp., Freehold, N.J.) and 0.5% trypsin solution in PBS (GIBCO, Grand Island, N.Y.) into the subcutaneous tissue of the dorsum. After 45 minutes, 5 ml of DMEM plus 10% FBS (#12-332-45; Flow Laboratories, McLean, Va.) was injected into the same area for neutralization of the enzymatic activity.

The fluid of the subcutaneous pouch was gently sucked and extruded three times and then was centrifuged at 2,000 rpm for 5 minutes. The pellet of cells was resuspended in complete DMEM and transferred to T75 flasks. The cultures reached confluence in 3 days and were passaged every 4 days. For the experiments the cells were utilized at confluence.

Angiogenesis test.—The angiogenic capacity of samples was evaluated by the rabbit cornea test, as previously described (*10*). One pocket about 2×3 mm was surgically prepared in the cornea of a rabbit. Special care was taken to have the bottom of this pocket at 2 mm from the limbus and to avoid any rupture of the pocket's walls. The material to be tested was introduced into the pocket either in the form of a pellet or as a cell suspension. The pellet assured slow release of the angiogenic stimuli, an essential condition for angiogenesis to occur (*11*). The pellet consisted of an ethylene-vinyl acetate copolymer (Elvax 40; du Pont de Nemours, Wilmington, Del.) prepared from a casting solution of 10% Elvax in methylene chloride. Under sterile conditions the test material was carefully incorporated by the polymer; then the methylene chloride was evaporated, and the repolymerized Elvax was cut into 1×1×0.5-mm pellets. Before use the pellets were kept under vacuum at 4°C overnight.

The cells were removed from the culture flask with 0.1% trypsin in PBS, washed twice in complete DMEM plus 10% FBS, and concentrated. A dose of 2×10^5 cells was used for each corneal implant. If the tension of the cornea was not reduced, a substantial number of cells were extruded from the pocket. To ensure retention, we aspirated about 50 μl of fluid with a 30-gauge needle from the anterior chamber of the eye before corneal implantation. The Elvax pellet, on the contrary, was easily retained within the corneal pocket when a slight pressure was applied after insertion.

The implants were examined daily with a slit-lamp Zeiss stereomicroscope. A slight corneal opacity was visible around the pocket after surgery, but it disappeared during the 2d day. For the angiogenesis-positive pellets, budding capillaries started to appear at day 4; by day 7 a dense network of newly formed vessels surrounded the pellet. For angiogenesis-positive cells, the budding capillaries appeared at the end of day 5 or at the beginning of day 6; by day 10 the implant was fully colonized by vessels. As a routine we considered as negative the implants unable to stimulate angiogenesis by day 7 for the pellets and by day 10 for the cells. Occasionally, a few capillaries could bud from the limbal vessels but were unable to reach the pellets. These implants were scored as negative.

Serial histologic sections were performed on corneas for each experiment so that we could exclude the possibility that the procedure induced an inflammatory process (fig. 3). To an expert examiner any inflammatory reaction is rapidly revealed by a change in the transparency of the cornea.

Removal of corneas for copper determination.—Special care was required for the evaluation of copper content in the corneas. The initial incision for performing the corneal pocket was done with a glass knife, and all instruments used were coated with a film of fluorocarbon (National Institutes of Health instrument shop) so that contamination would be avoided. The instruments were kept in a 30% HNO_3 solution and were washed exhaustively in sterile deionized water before use. The implant was observed twice daily. As soon as the capillary buds appeared on the limbal vessel, the cornea was removed. The rabbit was anesthetized, the eye was proptosed, and the cornea was frozen by the spraying of a solution of dichlorodifluoromethane (Criokwik 15145-266, VWR Scientific Div., UNIVAR, Baltimore, Md.). With a glass knife we then quickly removed the cornea by cutting about 0.5 mm above the limbus and carefully avoiding the vessels. The frozen corneas were stored in Dry Ice in plastic vials, previously washed with HNO_3 and deionized sterile water. Twenty corneas were utilized for each copper determination. To avoid contamination by blood, we removed all corneas before any vessels had migrated into the stroma. The frozen sample was transferred to a 70-ml Teflon pressure decomposition vessel (Uniseal; Columbia Organic Chemicals Co., Inc., Columbia, S.C.), treated with 1.0 ml high-purity concentration nitric acid, sealed with a Teflon cap inside a steel jacket, and heated for 16 hours at 125°C. We transferred the digested sample solution to a Teflon bottle with 5 ml deionized water to obtain a solution with a total volume of approximately 6.5 ml. We measured volumes with calibrated polypropylene pipettes.

Copper content of these sample solutions was determined by inductively coupled argon plasma-emission spectroscopy (model 975; Jarrell-Ash Div., Fisher Scientific Co., Waltham, Mass.). Copper emission was measured at 324.7 nm against copper standards prepared in 10% (vol/vol) nitric acid. Triplicate analyses were performed on each sample solution.

RESULTS

Angiogenesis by TIF

Walker carcinoma was implanted with the Millipore chamber in 30 rats. After 5–6 days when the tumors were 4–5 g and had incorporated the chambers, TIF was sampled. The fluid was removed under sterile conditions and collected in a single vial kept at +1°C during sampling. The composition of TIF, the conditions of the tissue surrounding the Millipore chamber, and the reasons supporting the belief that TIF represents the fluid bathing the neoplastic cells in vivo have been discussed in previous publications reported in (*8*). In this experiment the objective was to establish whether TIF was angiogenic or not.

The pooled fluid was subdivided in five samples of 1 ml each. Each sample was lyophilized, and the residue of each was incorporated into an Elvax pellet in the appropriate dose. The experiment was repeated with the use of the ethanol extract of TIF treated similarly.

TIF from MTW9A carcinomas was utilized in a similar set of experiments. The results indicate that both the fluid surrounding the neoplastic cells in vivo and the ethanol extract of this fluid are able to induce corneal neovascularization (fig. 1). Table 1 reports the relationship between dose of TIF and frequency of angiogenic response.

Angiogenesis by PGE$_1$

The content of E-type prostaglandins was measured in the interstitial fluid of MTW9A carcinomas by chloroform extraction, purification on silica gel, and specific prostaglandin radioimmunoassay (*12*). The fluid was sampled during the 5th day of tumor growth and was compared with the subcutaneous fluid of non-tumor-bearing animals matched for age and weight. The subcutaneous interstitial fluid was also removed 5 days after the implant of the Millipore chamber without tumor. In five of six determinations, the prostaglandin E content of the TIF was higher than that in normal subcutaneous fluid (table 2).

The angiogenic capacity of several prostaglandins was then tested. Known amounts of prostaglandins were added to a solution of Elvax in methylene chloride, and the pellets containing the appropriate dose were implanted in the cornea (table 3). In the positive implants, newly formed capillaries had penetrated the cornea by day 4, and a dense network was evident around the pellet by day 6 (fig. 2). If the pellet was removed, the capillaries started to regress within a few days.

TABLE 1.—*Angiogenic activity of TIF and its ethanol extract sampled from Walker carcinomas*[a]

Dose, mg/pellet[b]	TIF, positive/total	EtOH-supernatant, positive/total
0.1	2/6	4/6
0.2	2/4	6/6
0.4	—	5/5
0.5	4/6	4/4
1.0	4/5	—

[a] Similar data were obtained with TIF from MTW9A carcinomas.
[b] 1.0 ml of TIF corresponds to ≈34 mg of dry material.

TABLE 2.—*Prostaglandin E content of MTW9A TIF*[a]

Sample	Tumor	Subcutaneous tissue
1	1,376±121	592±119
2	998±76	959±64
3	1,073±57	321±15
4	1,148±84	147±6
5	669±40	304±21
6	995±57	110±5

[a] Values are means ± SD for three determinations in pg/ml. Prostaglandin E content of TIF was measured on samples removed from the tumor via a Millipore chamber (*7*) and compared with that of samples removed with an identical procedure from the subcutaneous tissue of rats on the same diet, matched for age and weight but without tumor. The determinations were done by Mrs. S. C. Liu in the laboratory of Dr. R. A. Knazek (*10*).

TABLE 3.—*Angiogenic activity of prostaglandins*

Prostaglandin	Doses and angiogenic activity, positive/total[a]					
	0.1 µg	0.25 µg	0.5 µg	1.0 µg	5.0 µg	10.0 µg
E$_1$	5/8	6/9	11/11	11/11	7/8	8/8
E$_2$	1/8	1/9	4/10	3/10	—	6/8
I$_2$	—	—	—	0/5	0/5	0/5
F$_{2\alpha}$	—	—	0/3	0/3	0/3	4/4

[a] Appropriate dose was incorporated into an Elvax pellet, and angiogenesis was scored at day 6. — = not done.

PGE$_1$ was able to induce the highest frequency of angiogenesis at the lowest dose when compared with angiogenesis induction by prostaglandins E$_2$, I$_2$, and F$_{2\alpha}$ (table 3). For both prostaglandins E$_1$ and E$_2$, a mobilization of inflammatory type of cells was not detected in serial histologic sections when the dose per pellet was equal to or less than 1 µg, and the cornea was examined at the end of day 3 after implantation. It is important to establish whether or not an infiltration of inflammatory type of cells is present before vessel invasion (fig. 3). After day 3 when the cornea is colonized by capillaries, one can find leukocytes in the surrounding stroma (*13*); but it is impossible at this time to determine whether they had migrated before the vessels colonized the cornea or whether they had merely escaped from the budding capillaries during vasculogenesis.

With the assumption that PGE$_1$ production was necessary for neovascularization to occur, we used indomethacin-treated rabbits in the angiogenesis test to ascertain whether a block of prostaglandin production impaired neovascularization (*14*).

Angiogenesis was produced by BALB/c fibroblasts, 2×10^5 cells for each corneal pocket. In an experiment to be reported in the following paper (*15*), it had been observed that normal fibroblasts of BALB/c skin cultivated in vitro lack angiogenic capacity for the first three to four passages. By passage 5 angiogenesis was induced by about 50% of implants, and by passage 8 almost all implants were angiogenic. After passage 15 the fibroblasts were able not only to induce angiogenesis but also to produce a sarcoma upon transplantation in the BALB/c donor.

Rabbits receiving indomethacin and untreated controls were implanted with fibroblasts of the first transfer generation unable to induce angiogenesis, fibroblasts of the 10th and 14th transfer generations, able to induce angiogenesis but not yet neoplastic, and fibroblasts of the 22d transfer generation, both angiogenic and oncogenic. As expected, the fibroblasts of the first passage were not angiogenic in both treated and untreated rabbits. However, passages 10, 14, and 22, strongly angiogenic in untreated rabbits, were unable to induce angiogenesis in the rabbits treated with indomethacin (table 4). The inability of passage 10, 14, and 22 fibroblasts to induce corneal neovascularization appeared to be due to lack of prostaglandin production, which is blocked by indomethacin.

Copper Content of Corneal Tissue During Angiogenesis

McAuslan and Reilly (*16*) reported that copper ions stimulated the mobility of bovine aortic endothelium in vitro. Since new formation of capillaries requires mobilization of endothelium, we determined whether an increment of copper ion concentration was detectable in the rabbit corneas before the capillaries had invaded the tissue. In one experiment 20 rabbits received in the right cornea an Elvax pellet containing 1 μg PGE$_1$ and in the left cornea a similar pellet containing 1 μg PGI$_2$. At this dose PGE$_1$ is angiogenic; PGI$_2$ is not and served as the control. At the end of day 3 post implantation, the animals were anesthetized and the corneas were removed. By day 3 the vessels of the limbal plexus facing the PGE$_1$ pellet started to bud but had not yet penetrated the cornea; thus contamination by blood carried by newly formed vessels was avoided. In a separate group of 10 rabbits the corneas were also removed without any previous treatment. Copper content was determined in the 3 groups, and corneas bearing the PGE$_1$ pellet were found to contain the largest amount of copper (table 5).

In a second experiment 20 rabbits received an Elvax pellet containing 1 μg PGE$_1$ in the left eye and an identical pellet in the right eye containing 1 μg PGE$_2$, poorly angiogenic at this dose. Each of another group of 20 rabbits was implanted with a pellet containing 1 μg PGI$_2$ in one cornea, whereas the contralateral cornea was left untreated. Also, in this experiment the copper concentration was elevated only in the PGE$_1$-treated corneas (table 5).

The concentrations of Ca, Fe, Mg, P, Zn, and K were not significantly changed in the samples utilized for copper determination.

Assuming that enhanced copper concentration in the corneas about to be invaded by capillaries was an indispensable event during angiogenesis, we used rabbits fed a copper-deficient diet to evaluate the angiogenic response induced by PGE$_1$ and BALB/c fibroblasts. Before being tested, the rabbits were fed the copper-deficient diet until the serum level of copper was about 50% lower than normal. Under these conditions the frequency of angiogenesis produced either by PGE$_1$ or by BALB/c fibroblasts was drastically reduced (table 6). Deficient rabbits showed a regular angiogenic response to PGE$_1$ challenge after they were returned to a normal diet for 3 weeks. The data suggest that the lack of copper impaired the angiogenic response.

TABLE 4.—*Block of angiogenesis by indomethacin*

Cell passage, 2×10^5 cells[a]	Indomethacin treatment,[b] positive/total	Controls, positive/total
1	0/7	0/5
10	0/7	13/15
14	0/10	14/17
22	0/8	8/8

[a] BALB/c fibroblasts from the subcutaneous tissue; 2×10^5 cells were in each implant.

[b] 25 mg/dose, three times a day for 6 days before and 8 days after grafting. Local treatment with indomethacin was also applied after grafting (see "Materials and Methods").

TABLE 5.—*Copper content of corneal tissue during angiogenesis*[a]

Expt No.	PGE$_1$	PGE$_2$	PGI$_2$	Untreated
1	80.7±0.4	—	60.0±4.8	58.6±1.0
2	68.5±2.3	55.5±5.4	51.4±1.8	48.1±3.9

[a] Values are means ± SD in μg/100 g. In experiment 1, PGE$_1$ (1.0 μg/pellet) and PGI$_2$ (1.0 μg/pellet) were implanted in the left and right corneas, respectively, of the same rabbit. A separate group of untreated rabbits served as the control. In experiment 2, PGE$_1$ (1.0 μg/pellet) and PGE$_2$ (1.0 μg/pellet) were implanted in the right and left corneas, respectively, of the same rabbit. In a second group of rabbits, PGI$_2$ (1.0 μg/pellet) was implanted in the right cornea, and the left cornea was left untreated. There were 20 corneas for each determination. $P = <0.005$ as compared to untreated.

TABLE 6.—*Angiogenesis in copper-deficient rabbits*

	Copper-deficient diet		Controls	
Angiogenic stimuli	Copper in serum,[a] μg/dl	Angiogenesis, positive/total	Copper in serum,[a] μg/dl	Angiogenesis, positive/total
0.5 μg PGE$_1$/pellet	54.4±8.0	1/11	99.3±8.3	9/12
1.0 μg PGE$_1$/pellet	54.4±8.0	1/11	99.3±8.3	11/12
BALB/c—fibroblast, 2×10^5	48.5±5.7	1/6	84.7±5.0	11/13
1.0 μg PGE$_1$/pellet	58.0±10	1/12	101.3±7.5	10/12[b]

[a] Rabbits were left on a copper-deficient diet until serum concentration of copper was about one-half the normal values (≈4 wk). Frequency of angiogenic response was drastically reduced in copper-deficient rabbits. Determination was done by Biometrics Medical Laboratory, Kensington, Md., using atomic absorption spectrophotometry.

[b] *Note* that the last group was constituted by rabbits kept on a copper-deficient diet for 4 wk and returned to a normal diet for 3 wk. Angiogenesis response was tested in the left cornea while the animals were on a copper-deficient diet and in the right cornea of the same animals after 3 wk on a normal diet.

Relationship Between PGE$_1$ Production and Copper Concentration During Angiogenesis

The results reported in the previous sections suggested that both PGE$_1$ and copper play a role in angiogenesis. Assuming that a cascade of events is necessary for angiogenesis to occur, we investigated whether PGE$_1$ production preceded or followed copper concentration in the cornea. To this end we assumed that an enhancement of copper content in the cornea could induce angiogenesis, and ceruloplasmin (human ceruloplasmin type III; Sigma Chemical Co., St. Louis, Mo.), the copper carrier protein of serum, was selected as an angiogenesis "factor." At a dose of 100 μg/Elvax pellet, ceruloplasmin induced angiogenesis in about 70% of corneal implants (12 positive implants/18). However, when the rabbits were treated with indomethacin, the ceruloplasmin-containing pellets were unable to induce angiogenesis (0 positive/15 implants). This observation suggests that the increment of copper concentration per se is not sufficient to induce angiogenesis and that prostaglandin production probably precedes copper mobilization.

DISCUSSION

The experiments showed that the fluid surrounding the neoplastic cells in vivo had the capacity to induce corneal neovascularization when incorporated as lyophilized material into a slow-release polymer. The angiogenic capacity was manifested by the complete fluid as well as the ethanol extract of TIF. Culture media of several types of cells, neoplastic or not, have been previously shown to possess the capacity to induce neovascularization or to stimulate growth of the endothelium (*17–21*). Our experiments established that in vivo angiogenic factor(s) are also released in the fluid surrounding the cells. This observation suggests that the often visible halo of "hyperemia" and vascular proliferation observed around nodules of tumors growing in the mesenterium or other surfaces may be due to TIF, which oozes at the periphery of the node and stimulates vessel proliferation in the surrounding tissue.

The presence of angiogenic stimuli in the fluid surrounding a tumor is also important for diagnosis of neoplasia. For instance, Tapper et al. (*22*) described angiogenic activity in ocular fluid in contact with retinoblastomas, and Chodak et al. (*23*) described angiogenic activity in the urine of patients with carcinomas of transitional epithelium.

Prostaglandin E content of TIF was higher than that of the interstitial fluid from the normal subcutaneous area where the tumor was implanted. Consequently, we tested the angiogenic capacity of several prostaglandins and observed that PGE_1 was the most effective inducer of neovasculogenesis.

We assumed that the release rate of each prostaglandin from the pellet was similar on the basis that the pellet preparation was identical for all of them. Since removal of the pellet was followed by regression of the newly formed capillaries, persistence of the prostaglandin gradient seems necessary not only for the onset of neovascularization but also for the maintenance of the capillary network. We also assumed that the prostaglandin dose found in each pellet could maintain this gradient during the 5–6 days necessary for the test to be completed. Under our experimental conditions, however, a difference in prostaglandin lability may alter the dose-response profile observed.

A PGE_1 dose of 1 µg/pellet or less was unable to stimulate any appreciable inflammatory response, but it induced a strong neovascularization. Inflammatory type cells have been shown to be highly angiogenic (*24–26*); however, the experiments with low doses of PGE_1 indicated that angiogenesis could be obtained without inducing an inflammatory response as evaluated on serial sections of the corneal implants (fig. 3). The interpretation that PGE_1 plays the role of a mediator in angiogenesis (*13, 27*) was sustained by the experiment in which corneal neovascularization was induced by fibroblasts. Cultured skin fibroblasts were not angiogenic for the first three passages, but from passage 4 onward they became angiogenic (*15*). Neovascularization of the cornea was induced by the fibroblasts without mobilization of inflammatory cells, and in rabbits treated with indomethacin angiogenesis failed to develop; these findings suggest that prostaglandin production was the missing link in the process. An effective block of angiogenesis could be obtained only when the indomethacin treatment followed the procedure described in "Materials and Methods."

The work of McAuslan and Reilly (*16*) on copper ions and mobility of endothelium suggested to us the possibility that copper was involved in the corneal penetration by capillaries. We found that in PGE_1-treated corneas copper accumulation occurred before the capillaries penetrated the cornea. Indeed, rabbits on a copper-deficient diet implanted with PGE_1 or fibroblasts were unable to mount an angiogenic response, provided that copper in serum was lowered to about one-half the normal level or less. Both findings, coupled with the observation that the angiogenic response returned to normal when copper-deficient rabbits were returned to the standard diet, suggest that mobilization of copper ions is involved in neovascularization.

On this assumption we tested the angiogenic capacity of ceruloplasmin, the copper carrier of serum. We found that ceruloplasmin was able to induce neovascularization of the cornea but at a relatively high dose, probably because only a fraction of the molecule carries the active site (*28*). Indeed, ceruloplasmin deprived of copper lacked angiogenic capacity (Raju KS, Alessandri G, Ziche M, Gullino PM: Unpublished data). The angiogenic capacity of ceruloplasmin was utilized so we could evaluate whether PGE_1 production and copper accumulation were interdependent. We found that ceruloplasmin lost the angiogenic capacity in rabbits treated with indomethacin. This finding suggests that prostaglandin production probably precedes copper concentration.

The biologic significance of these two events during neovascularization is not clear. Cu^{2+} added to homogenates of sheep vesicular tissue has been shown to stimulate conversion of arachidonic acid into prostaglandins (*29, 30*). In a preliminary experiment we were unable to find substantial changes in arachidonic acid content of corneas during fibroblast-induced angiogenesis.

Growing tumors have been found to produce prostaglandins of the E-series not only in our models but also in other natural and induced tumors (*31*). In sarcomas induced by Moloney virus, prostaglandin production was sufficiently high to cause bone deformities (*32*). Moreover, several examples have been reported of reduction of tumor growth by suppression of prostaglandin synthesis (*14, 31, 33, 34*). Investigators observed that growing tumors have substantially increased ceruloplasmin levels in blood (*35, 36*), and for Walker carcinoma a direct correlation has been found between increment of copper concentration in plasma and $[^3H]$thymidine uptake (*37*). Endothelium from umbilical and mesenteric arteries and veins produces in vitro prostaglandins of the F- and E-series. Synthesis is decreased by aspirin-like agents, but it is enhanced by vasoactive substances (*38, 39*), and bradykinin in particular appears to selectively increase prostaglandin-like agents in arteries and prostaglandin-like substances in veins (*40*).

All these observations suggest that the interdependence between PGE_1 production and copper mobilization during angiogenesis is a plausible event. One must be aware, however, that mammalian cells seem to disgorge prostaglandins at the slightest provocation. It seems, therefore, unlikely that the simple release of a prostaglandin can by itself initiate and direct a specific response of cell populations able to complete a morphogenetic event, such as the formation of a capillary network. Yet from the knowledge accumulated since Folkman promulgated the notion that angiogenesis and tumor growth are interdependent (*1*, *41*), one has the impression that neovascularization results from a cascade of events that presumably follow a pattern. The data reported here indicate that PGE_1 and copper are part of this cascade.

Angiogenesis and Neoplastic Progression In Vitro [1,2]

Marina Ziche [3,4] *and* **Pietro M. Gullino** [3,5,6]

ABSTRACT—In vivo cell populations at high risk of neoplastic transformation have been shown to acquire the ability to induce new formation of vessels. The present experiments tested whether the same change occurred during neoplastic transformation in vitro. In four cell populations (human HBL 100 mammary epithelium, BALB/c fibroblasts, C57BL-MG epithelium, and Syrian golden hamster embryo cells), angiogenic capacity appeared during their cultivation in vitro and was evident long before a neoplastic transformation could be recognized. The data were interpreted to support the hypothesis that acquisition of angiogenic capacity by a cell population normally devoid of this capacity indicates an increased risk of neoplastic transformation.—JNCI 1982; 69:483–487.

Previous work performed in our laboratory showed that in vivo the hyperplastic epithelium of the human mammary gland acquired the ability to induce neovascularization in about 30% of specimens tested at random (*1*). No other known characteristics distinguished the angiogenesis-positive specimens from the remaining 70% lacking angiogenic capacity. Because a high percentage of human primary mammary carcinomas are angiogenic but normal, adult mammary tissue is not (*1–3*), we hypothesized that the capacity to induce neovascularization is a property acquired by cell populations progressing toward neoplastic transformation.

The validity of this hypothesis was tested under two experimental conditions in which the risk of neoplastic transformation was predictable. The first concerned hyperplastic outgrowths of mouse mammary gland. These outgrowths are often transplantable in the inguinal fat pad free of mammary parenchyma. Medina (*4*) developed two lines, D_1 and D_2, morphologically identical but different in the frequency of neoplastic transformation (<10% in the D_1 line and >40% in the D_2 line). We observed that long before any neoplastic transformation was demonstrable, the D_2 line, at higher risk of neoplastic transformation, induced angiogenesis at a frequency twice as high as that of the D_1 line at lower risk (*5*).

In another experiment we took advantage of the observation of Brand (*6*) and Brand et al. (*7*) on oncogenesis by plastics. In the subcutaneous tissue of CBA mice, large (25×15×0.2 mm) plastic cover slips produced sarcomas in a higher number and at an earlier date than did smaller (15×7×0.2 mm) cover slips. We observed that within a few weeks after implantation in the same mouse, the cells attached to the large cover slip induced angiogenesis at a frequency severalfold higher than cells attached to the small cover slip. This was observed long before any tumor was present or was expected to occur (*8*).

The experiments reported here were performed to establish *a*) whether cells undergoing neoplastic transformation in vitro acquired angiogenic capacity in the process and *b*) whether onset of the angiogenic capacity occurred before oncogenesis, defined as the ability to produce a tumor upon transplantation. The major objective was to corroborate the hypothesis generated by the experiments with hyperplastic outgrowths (*1–3*) and plastic cover slips (*8*), namely, that a cell population, normally lacking angiogenic capacity, is at higher risk of becoming neoplastic when it has acquired angiogenic capacity. Moreover, if the angiogenic capacity is acquired before oncogenesis is demonstrable, it may reveal a preneoplastic condition and have prognostic value.

MATERIALS AND METHODS

Human line.—The HBL 100 line of human mammary epithelium was utilized for the angiogenesis test at passages 6, 23, and 130. This line was developed from the milk of a 27-year-old Caucasian obtained at day 3 after delivery (Gaffney EV: Personal communication). The primary culture of the milk-cell pellet was initiated in McCoy's 5-A medium supplemented with 10% FBS and was characterized by a number of mitoses higher than usual. At passage 5 enough cells were available for characterization. Metaphases contained human chromosomes in numbers ranging from 58 to 72. In later passages the range was 58–67, and the mode was 63. HeLa marker chromosomes were absent. The cells in culture were able to produce a small amount of lactose but not α-lactalbumin. They possessed human type B glucose-6-phosphate dehydrogenase activity.

At passage 12, HBL 100 grew rapidly in soft agar (0.3%) supplemented with 10% FBS. Inocula of 10^7 cells in 0.4 ml McCoy's 5-A medium from passages 9–20 failed to produce tumors in Swiss athymic mice receiving the implants ip or iv or in the cleared fat pad and observed for 14 months. Carcinomas consistently appeared when passage 103 or later passages were inoculated (10^7 cells) in the mammary fat pad. After passage 35, HBL 100 produced tumors occasionally when inoculated intracerebrally in untreated Swiss

athymic nude mice or sc in nude mice heavily treated with antilymphocyte serum (*9*).

The milk donor was followed for 6 years with clinical and mammographic evaluations at regular intervals, but the presence of a breast carcinoma was never revealed.

Murine lines.—Fibroblasts were harvested from the subcutaneous tissue of BALB/c male mice that were 6 weeks old and had been raised on standard Zeigler diet (Zeigler Bros., Gardners, Pa.). About 3 ml of a phosphate-buffered saline solution containing 0.5% bacteria collagenase (Worthington Biochemical Corp., Freehold, N.J.) and 0.5% trypsin (GIBCO, Grand Island, N.Y.) was injected sc into the dorsal region. The solution was left for 45 minutes, and then 5 ml of DMEM was injected into the same area. Slowly, the culture medium was sucked in and out of the syringe several times to "wash out" the pouch produced by the initial injection of lytic enzymes. The fluid collected from 3 mice was pooled and centrifuged at about 2,000×*g*, and the pellet containing the fibroblasts was washed and resuspended in DMEM supplemented with 10% fetal calf serum and seeded in T75 plastic flasks (Falcon Plastics, Oxnard, Calif.). The fibroblasts reached confluence in 3 days and were passaged every 4–5 days. For the determination of angiogenic capacity the cultures were tested at day 4.

The C57BL-MG line was obtained from Dr. D. K. Howard (*10, 11*) and was originally developed by Vaidya et al. (*12*) from the mammary gland of a 23-week-old C57BL/6 female. The cells had epithelial morphology and were cultivated in HMEM containing 10 μg insulin/ml and 10% FBS. From passage 31 of the parent line, Howard et al. isolated several clones by end-point dilution. Three of these clones indicated as 2, 18, and 22 were readily susceptible to MuMTV infection (*10, 11*) and were utilized for tests of the effect of MuMTV infection on angiogenesis.

The infected cells were unable to produce a tumor when they were injected sc into the mammary fat pad of athymic nude or syngeneic mice. The MuMTV-infected clones become tumorigenic only when treated with appropriate doses of 7,12-dimethylbenz[*α*]anthracene (*11*). Clones 2, 18, and 22, MuMTV infected and uninfected, as well as the uninfected parent line and clones 1 and 3 were tested for angiogenic capacity at several passages.

Hamster embryo line.—From 72-day-old Syrian golden hamster embryos, Dr. Kirby developed a line that was cultivated in complete DMEM for 16 passages (*13*). At this time the cell population was cloned by end-point dilution, and clone 220D6 was selected because it had the least "abnormal" morphology. Two sublines, designated A and B, were separated from clone 220D6 and subcultured twice weekly with a 1:40 split ratio. Dr. Kirby compared the two lines for serum dependency, plating efficiency, ability to grow in 0.32% agar, and tumor formation by 10^6 cells inoculated sc into 4-day-old Syrian golden hamsters. The objective was evaluation of the appearance of new properties in cell populations derived from the same clone and undergoing simultaneous neoplastic transformation in vitro. We utilized both clones at several passages, preserved frozen, to compare the angiogenic capacity with their ability to grow in agar and to be tumorigenic upon transplantation.

Angiogenesis test.—Angiogenesis was evaluated by the rabbit cornea test as previously described (*14*). A 2×3-mm pocket was prepared in the cornea of an adult New Zealand White rabbit, male or female. The bottom of the pocket must be 1.5–2.0 mm from the limbus. A 30-gauge needle was inserted into the anterior chamber of the eye, and about 50 μl of fluid was removed to partially collapse the cornea. Then 1–2×10^5 cells in 5–10 μl medium were injected into the corneal pocket, and a slight pressure was exerted so the open border of the pocket would collapse. Reduction of corneal tension is indispensable to ensure retention of a sufficient number of cells to start a colony. About 5 days after implantation, a whitish area was visible around the pocket examined with a slit-lamp stereomicroscope. In positive tests sprouts of capillaries started to penetrate the cornea from the limbus by days 5–6, and by day 10 a bunch of newly formed capillaries was clearly visible (figs. 1A, 1B). Implants unable to induce neovascularization by day 10 were scored as negative. For each experiment a few corneas were removed for histologic examination. Occasionally, a few capillaries could bud from the limbal vessels but were unable to colonize the implant. They were scored as negative. Surgical procedures were performed under Nembutal anesthesia (30 mg/kg). Daily evaluation of the angiogenic response with the slit-lamp stereomicroscope did not require anesthesia. Strict asepsis is indispensable at every step of the procedure. After cells were grafted, each rabbit was given an injection im of 20 mg triamincinolone acetonide/kg body weight; this chemical is a synthetic corticosteroid with a marked anti-inflammatory action that minimizes the possible interference of an inflammatory reaction.

RESULTS

Mammary human line.—The angiogenic capacity of HBL 100 was evaluated for three passages and compared with the tumorigenicity as tested in the Swiss athymic nude mice. Table 1 shows that passage 6, which consistently failed to produce tumors upon transplantation or to grow in soft agar, was already angiogenic. Passage 23 elicited an angiogenic response but no tumors, and passage 130 consistently produced rapidly growing tumors and was consistently angiogenic. HBL 100 represents one example of a human line of mammary epithelium in which angiogenic capacity was present long before a neoplastic transformation could be demonstrated in the original donor or after transplantation in athymic nudes. In the past it had been demonstrated that normal adult human mammary tissue is not angiogenic (*1*).

Fibroblasts of BALB/c mice.—The objective of these exper-

TABLE 1.—*Angiogenesis and tumorigenicity of HBL 100 cells at different passages*

[a] The medium without cells was not angiogenic.

[b] Each of 20 mice received 10^7 cells injected ip or sc.

iments was comparison of the angiogenic capacity of subcutaneous fibroblasts maintained in culture from passage 1 onward, until a sarcoma could be induced upon transplantation into the syngeneic host. In three experiments we found that angiogenic capacity was absent for the first two to three passages, it was detected at passages 3–4, and it was present in almost every implant by passages 7–10 (table 2). Sarcomas developed only after passage 15, never at passage 10 or earlier. In this experimental system, as for the human mammary line HBL 100, angiogenesis appeared long before any neoplastic transformation was detectable.

C57BL/6 mammary epithelium.—The objective of these experiments was to ascertain whether mouse mammary epithelium acquired angiogenic capacity in culture and whether infection with a MuMTV influenced the angiogenic response. The parent line at the time of cloning was at the 31st passage and already showed angiogenic capacity. Since normal adult mammary mouse epithelium is not angiogenic (*2, 5*), the capacity to induce neovascularization was acquired during the cultivation in vitro, although the exact time of appearance could not be ascertained. The four clones tested had about the same angiogenic capacity as that of the parent line. The MuMTV infection of three clones did not induce any striking modification of the angiogenesis pattern (table 3). A small increase of angiogenic activity after MuMTV infection was observed in all three experiments, but the difference was so slight that an extensive analysis was considered unwarranted. Transplantation of these cells never produced a tumor.

The experiment with subcutaneous fibroblasts (table 2) showed that the angiogenic response increased in frequency as the number of passages in cultures increased, and by the time the cells produced a tumor, practically all implants were angiogenic. We could not detect the same behavior in the C57BL mammary epithelium. For instance, the angiogenic activity of clone 2 at passage 16 was not substantially different from that of clone 2 at passage 24; the same can be said for clone 18 at passage 16 versus passage 28 (table 3). This question was more carefully analyzed with hamster embryo cells.

Hamster embryo cells.—Two cell populations from the same clone were cultured under identical conditions, and their angiogenic capacity was compared at subsequent passages with the ability to grow in 0.3% agar and to form tumors. Angiogenesis appeared in both cell populations before the capacity to grow in agar or to produce tumors was established (table 4). The number of implants showing an angiogenic response did not change appreciably as the number of passages in culture progressed. In these cells, as for the mammary epithelium of C57BL/6 mice, not every implant was angiogenic when the neoplastic transformation was established.

[a] The formation of a sarcoma after transplantation of 10^7 cells in the subcutaneous tissue of the interscapular region appeared after passage 15 for line I, after passage 20 for line II, and after passage 21 for line III. Capacity to induce angiogenesis in all three lines already appeared at the third to fourth passage.

[a] Each 4-day-old hamster was inoculated sc with 10^6 cells; 10 animals were in each group (*13*).

DISCUSSION

Since the observation that a neoplastic cell population could form a tumor only when new formation of vessels was elicited from the host (*15, 16*), angiogenesis was studied by oncologists mainly with the objective of finding the factor(s) involved in the process (*17–19*). The majority of adult tissues where tumors originate are not angiogenic, but the neoplastic tissues are; therefore, the capacity to elicit new formation of vessels is acquired during neoplastic transformation. Cultivation in vitro represents a special condition for mammalian cell populations known to favor neoplastic transformation in a large number of cases. In four cell populations cultivated in vitro, we observed that angiogenic capacity appeared long before the neoplastic transformation was demonstrable by transplantation in vivo. Consequently, the appearance of angiogenesis in a tissue normally devoid of it should indicate that a step toward neoplastic transformation has occurred. The presence of an angiogenic response before the neoplastic transformation could be demonstrated was unequivocal in the four experimental models utilized here. The early appearance of angiogenic capacity during neoplastic transformation is therefore a property expressed under in vitro conditions as it was previously observed in vivo (*1, 3, 5, 8*).

The question as to whether MuMTV infection of mammary epithelium is a determinant factor in eliciting angiogenic capacity could not be answered in a satisfactory manner. The C57BL/6 parent line went through 31 culture passages before cloned cell populations capable of being infected by MuMTV were obtained. The in vitro cultivation was sufficiently long to induce an already high frequency of angiogenic response in the uninfected clones. The MuMTV infection failed to enhance the angiogenic response of the clones to a sufficiently high frequency to convincingly indicate that MuMTV played a decisive role in inducing angiogenic capacity of infected cells.

The interdependence, if any, between angiogenesis and oncogenesis is still difficult to envisage. In vivo we have observed that tumors were highly angiogenic; however, a fraction of tumor fragments was consistently unable to induce angiogenesis (*1, 2, 3, 8*). Cultured neoplastic cells were also highly angiogenic; however, several implants also were unable to elicit neovascularization. Thus angiogenesis does not appear to be an obligatory property of every neoplastic cell in a tumor. Heterogeneity of the tumor cell population is a well-known event and may be responsible for this finding.

Since angiogenic capacity appears early during oncogenesis, one would expect a gradual increment in the number of angiogenesis-positive implants as the time of neoplastic transformation approaches. This phenomenon, however, was observed only for the subcutaneous fibroblasts (table 2) and not for human and mouse mammary epithelia or for hamster embryo cells in culture. Similarly, the above correlation was not observed in vivo for hyperplastic outgrowths of murine mammary glands (*2*) or for cells around plastic cover slips producing sarcomas (*8*). An interdependence between angiogenesis and oncogenesis is not demonstrable at this time; however, it is clear that angiogenic activity appears consistently in a variety of cell populations before neoplastic transformation is evident, either in vitro or in vivo.

The possibility of using angiogenesis as a marker of a cell population at high risk of neoplastic transformation or of a cell population already tumorigenic is presently hampered by our limited knowledge of the sequence of events necessary for angiogenesis to occur. However, two observations of clinical importance are already available. Because neoplastic cells in vivo release the angiogenic factor(s) into the surrounding fluid, the presence of a tumor can be revealed by the angiogenic capacity of fluids bathing the tumor: Tapper et al. (*20*) reported this observation for retinoblastomas, and Chodak et al. (*21*) reported it for bladder carcinomas.

Immunization Against Transplantable Leukemia Impaired in Copper-Deficient Mice [1,2,3]

Omelan A. Lukasewycz [4] *and* Joseph R. Prohaska [5,6]

ABSTRACT—Inbred C58 mice, kept on a copper-deficient (−Cu) diet from birth, were tested for their ability to be immunized to, and subsequently challenged with, line I_b syngeneic transplantable malignant lymphocytes (I_b cells). −Cu mice had significantly lowered hematocrits and serum ceruloplasmin (EC 1.16.3.1) values in contrast to those of the copper-supplemented (+Cu) controls. All male +Cu mice (17/17) survived the immunization regimen (consisting of $\approx 10^3$ viable and 10^7 inactivated I_b cells) and the challenge dose (10^6 viable I_b cells). Male −Cu mice had a survival rate of only 15% (4/27) after the immunization process and an overall survival rate of 11% (3/27). Female +Cu mice had survival rates of 86% (19/22) after immunization and of 74% (14/19) after the challenge dose, compared to 54% (15/28) and 47% (7/15) survival rates, respectively, for the female −Cu mice. Overall, the +Cu mice had a 79% (31/39) survival of both immunization and challenge compared to an 18% (10/55) survival for the −Cu mice. These results indicate that the initiation and maintenance of cell-mediated immunity to leukemia cells are severely impaired in −Cu animals.—JNCI 1982; 69:489–493.

We have utilized a mouse model, the C58 mouse-line I_b syngeneic leukemia system, to evaluate and characterize the lymphoid subpopulations operative in leukemia immunity (*1-5*). Immunity in this model is predominately cellular in nature (*3, 6*) and is mediated by a lymphocyte cell population that appears to consist of Thy 1.2$^+$, surface immunoglobulin-negative, Ly 4.2$^-$ T-cells (*3, 4*) that possess the Ia determinants (*5*).

Appropriate nutrition is crucial to the well-being of any organism. Malnutrition has been shown to have a profound influence on both the humoral and cell-mediated immune responses (*7*). Martinez et al. (*8*) have shown that starvation, even for 48 hours, will severely suppress cellular immunity in the C58-I_b system. Investigators in our laboratory have recently shown that an impaired humoral immune response is observed in mice with severe as well as marginal −Cu and that the magnitude of this impairment is highly correlated with the degree of functional −Cu (*9*). We thus wished to explore the effect of −Cu on the cellular arm of the immune system, and we describe here the effect of −Cu on the cell-mediated immunity to syngeneic malignant lymphocytes.

MATERIALS AND METHODS

Mice.—Inbred C58 mice, originally from Dr. William H. Murphy Jr., Department of Microbiology, University of Michigan Medical School, Ann Arbor, Mich., have been maintained at the animal facilities of the School of Medicine, University of Minnesota, Duluth, Minn., since 1975.

Pregnant dams were housed in polyethylene cages with stainless steel covers and wood shavings (American Excelsior Co.) for bedding. Offspring were transferred at 3 weeks of age to stainless steel cages with wire mesh floors. Mice were used in I_b immunization experiments at 5–9 weeks of age.

Diet.—On the day of parturition, C58 dams were switched from a nonpurified diet (Purina Mouse Chow; Ralston Purina Co., St. Louis, Mo.) containing 12 mg Cu/kg to a purified mouse diet, formulated to omit Cu from the salt mix (modified AIN-76; Teklad Inc., Madison, Wis.) and containing no more than 0.6 mg Cu/kg. This diet has previously been used to establish −Cu in mice (*10*). Approximately half of the dams were given supplemental Cu (20 $\mu g CuSO_4$/ml) in the drinking water, whereas the remaining dams were given deionized water to drink. Pups were maintained on the diet of their respective dams until the experiments began. +Cu and −Cu animals were matched for age, sex, and weight for each experiment.

Hematocrit.—Hematocrit determinations were done by retro-orbital bleeding of etherized mice into heparinized microhematocrit capillary tubes (Scientific Products).

Ceruloplasmin levels.—Plasma from individual microhematocrit tubes was assayed for ceruloplasmin (EC 1.16.3.1) activity, with *o*-dianisidine as substrate as described by Prohaska (*10*). Ceruloplasmin, a cuproenzyme, was routinely used to monitor Cu status of the mice (*9*).

Line I_b cells.—The origin of I_b syngeneic malignant lymphocytes was described by Lin et al. (*6*). Fresh suspensions of I_b cells were prepared by aseptic removal of spleens from C58 mice moribund with transplanted leukemia frozen stock (passage 79); spleens were then injected with HBSS, sectioned with scalpels, and a single cell suspension prepared.

ABBREVIATIONS USED: −Cu=copper-deficient (deficiency); +Cu=copper-supplemented; HBSS=Hank's balanced salt solution; LD$_{50}$=median lethal dose.

Gross particles were discarded and cells were washed two more times in HBSS (250×*g* for 5 min each). Total and viable cell counts by trypan blue exclusion (*11*) were performed at this time.

I_b cells treated with Formalin.—Cells were prepared by dilution of I_b cells in HBSS to a concentration of 2×10^7 cells/ml and then diluted 1:2 with a 1:250 dilution of a Formalin solution (37.4% analytical grade formaldehyde solution diluted 1:10 in HBSS). Cells were incubated with the Formalin solution (final dilution 1:500) at 4°C for 18 hours and then used for immunization of mice.

This Formalin treatment results in a preparation that still harbors approximately 1×10^3 viable cells from the initial 1×10^7 I_b cell load; i.e., Formalin inactivates 99.999% of all the cells (*6*). This preparation is highly immunogenic and will protect normal mice against a subsequent challenge of at least 1×10^7 viable I_b cells ($LD_{50}>1\times10^7$ viable I_b cells); mice immunized with preparations that harbor no viable cells die at lower challenge doses ($LD_{50}=1\times10^{5.9}$ viable I_b cells) (*1*). Nonimmunized mice will succumb to challenge of a single viable I_b cell (*6*). There is a linear relationship between time of death and the $\log_{10}$ dose of viable I_b cells administered (*1*).

Immunization and challenge of mice.—Mice received a single 1.0-ml ip injection of cells treated with Formalin as an immunization regimen. Immunocompromised mice will succumb to the viable I_b cells that remain in the "Formalinized" cell preparation (*2*). Mice were observed for 21 days for determination of leukemia deaths due to the immunizing preparation. All deaths recorded in these experiments were consistent with the time course and gross pathology of I_b leukemia. A challenge dose was administered 3 weeks after immunization; it consisted of a 1.0-ml ip injection containing 1×10^6 viable I_b cells. These animals were then followed for an additional 15 days to ascertain leukemia deaths. Dose-response experiments were conducted in unimmunized mice, both in controls and in −Cu animals, by the injection of viable I_b cells into mice of each group at each of three doses—10^3, 10^5, and 10^7 cells. Leukemia deaths were monitored twice daily.

Statistics.—Hematocrit and ceruloplasmin means were compared with the use of the *F*-variance ratio and two-tailed Student's *t*-test. Survival data were treated by chi-square analysis. Linear regression analyses were performed on the dose-response data.

RESULTS

The effect of dietary −Cu was manifest quite rapidly in both hematocrits (text-fig. 1) and ceruloplasmin levels (text-fig. 2). Hematocrit levels of −Cu mice were below those of +Cu mice as early as 1 week after weaning (wk 4). The hematocrits in −Cu mice tended to decrease further during weeks 5–7. The decreased hematocrits appeared much more pronounced in the −Cu male population compared to those in females.

Ceruloplasmin values, determined on the same group of mice, also show a decrease by week 4. During the subsequent weeks ceruloplasmin levels began to increase, especially among −Cu females, and possibly approached +Cu values by week 10. We have found that the hematocrit and ceruloplasmin values varied in individual −Cu mice, even though they were treated identically from birth. Animals were selected for further study based on the time course of their Cu depletion.

The effect of −Cu on immunization to I_b cells and subsequent challenge was studied in −Cu mice and compared to that in +Cu mice (table 1). Male +Cu mice responded exactly as did Cu-adequate (chow-fed) mice studied previously (*1*), i.e., a 100% survival of the immunization and challenge regimens. Male −Cu mice, however, showed only a 15% survival of immunization and an overall survival rate of only 11%. All deaths recorded in these experiments were

Total +Cu	—	—	36/39 (92)	—	—	31/36 (86)	31/39 (79)
Total −Cu	—	—	19/55 (35)[g]	—	—	10/19 (53)[h]	10/55 (18)[g]

[a] Table is a composite of three replicate experiments with male and female mice.

[b] Preimmunization determinations performed 24 hr before immunization regimen was started.

[c] Postimmunization determinations performed 15–20 days after immunization and therefore included only survivors of the regimen.

[d] Immunization regimen consisted of ip injection of 1.0 ml Formalinized cells containing ≈10^7 inactivated and 10^3 viable I_b cells. Survivors were scored over a 15-day period.

[e] Challenge dose contained 1×10^6 viable I_b cells in a 1.0-ml ip bolus. Survivors counted at a 15-day end point.

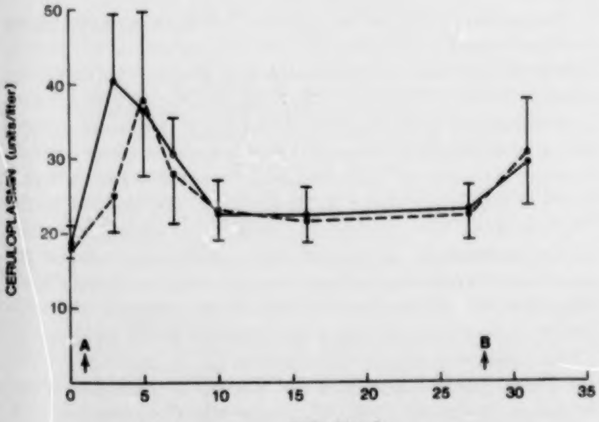
[f] Means are significantly different from controls (+Cu) $P<0.001$, by Student's *t*-test.

[g] Significantly different from controls (+Cu), $P<0.01$, by chi-square test.

[h] Significantly different from controls (+Cu), $P<0.05$, by chi-square test.

consistent with the time course and gross pathology of I_b leukemia. Female +Cu mice also exhibited a high survival immunization (86%) as compared to that of female −Cu mice (54%). More than half of the −Cu females that survived immunization failed to survive the challenge of 10^6 viable I_b cells. Only 7 of 28 (25%) of the −Cu females survived immunization and challenge as opposed to 64% survival (14/22) of +Cu females. The totals indicate that the +Cu mice fared very well in contrast to the −Cu mice in immunization (92 vs. 35%) and challenge (86 vs. 53%) survival rates. The overall picture is even more striking: 31 of 39 (79%) +Cu mice survived both immunization and challenge compared to 10 of 55 (18%) −Cu mice.

We observed that survivors of immunization, both +Cu and −Cu animals, had near normal hematocrits and higher ceruloplasmin values than those seen prior to immunization (table 1). This increase was not due to induction of ceruloplasmin from the Cu contained in the Formalinized I_b preparation. Replicate samples of the immunization preparation were analyzed by atomic absorption spectroscopy after wet ashing in HNO_3. The immunization bolus contained 0.045 μg Cu, an amount equal to only 5% of that which a mouse would absorb in 1 day from the low Cu diet. Therefore, a different mechanism seemed plausible.



TEXT-FIGURE 3.—Plasma ceruloplasmin activity of normal, chow-fed C58 mice after inoculation of Formalinized I_b cells (●) or the Formalin vehicle alone (■). Values are the means ± SD of 12 animals (6 males and 6 females). Both groups A) were given injections on day 1 of their respective treatments, and B) all mice were challenged on day 28 with 10^6 viable I_b cells. All unimmunized animals died within 6 days after administration of the challenge dose (by day 33).

The capacity of the I_b immunization preparation and its Formalin vehicle to induce serum ceruloplasmin was determined in chow-fed animals (text-fig. 3). After immunization with I_b cells, C58 mice demonstrated a rapid 221% rise in ceruloplasmin activity ($P<0.01$), which subsequently fell but remained elevated (126%) even 26 days after injection ($P<0.01$) (text-fig. 3). The Formalin-injected mice also showed a rapid rise in ceruloplasmin activity; however, 2 days after injection the Formalin-treated mice had lower ceruloplasmin activities than those given injections of I_b cells ($P<0.01$). This difference was eliminated by day 5, and as with I_b-immunization, the Formalin treatment also caused a prolonged 125% elevation of ceruloplasmin activity (text-fig. 3). Challenge with I_b cells further increased plasma ceruloplasmin activity ($P<0.01$) in both immunized and Formalin-treated animals (text-fig. 3). All unimmunized animals (i.e., those given only the Formalin vehicle) were dead of leukemia within 6 days after administration of the challenge dose. The increases from prechallenge levels were equivalent in I_b-treated (129%) and Formalin-treated mice (138%). Males and females gave equivalent responses to the injection regimens.

Nutritional factors may modify the sequence of events leading to death by malignant lymphocytes. Accordingly, a study was conducted to determine the time course of death from the I_b leukemia in −Cu mice compared to that in +Cu controls (table 2). There were no significant differences in the time of death at any of the three doses employed. Furthermore, linear regression and slope analysis demonstrated that both groups responded similarly.

TABLE 2.—*Effect of −Cu on survival times of nonimmunized mice to line I_b malignant lymphocytes*[a]

Dose of viable I_b cells	Time of death, mean days ± SD (No. of mice)	
	+Cu	−Cu
10^3	9.8±1.6 (8)	10.0±0.8 (11)
10^5	6.9±0.5 (9)	7.4±0.6 (11)
10^7	4.6±0.9 (10)	4.7±0.7 (12)

[a] Each mouse received a single ip injection of the appropriate dose; survival and death due to leukemia were evaluated twice daily. All mice died of leukemia. Mean comparisons were made by Student's *t*-test, and no significant differences were observed.

DISCUSSION

−Cu in animals is known to lead to alterations in several biologic systems—hematologic, cardiovascular, central nervous, and skeletal. The immune system should now be added to this list. The severity of the alterations depends, to a large extent, on the degree of deficiency and the sensitivity of the system to Cu depletion. The immune system must be very sensitive to Cu depletion because profound effects on both humoral (*9*) and cell-mediated immunity (table 1) are observed in −Cu mice that display only modest changes in the other biologic systems sensitive to Cu deprivation.

Unlike dietary −Cu in other species, mice show variable responses to treatment as determined by hematocrit values (text-fig. 1) and plasma ceruloplasmin activities (text-fig. 2). This variable response of mice to the −Cu diet has been noted previously (*9*) and most probably reflects the individual animal's unique growth requirement. Contributing to this variability is the amount of Cu transferred during lactation and the efficiency in metabolizing the small amount of Cu that remains in the purified diet.

Despite individual variability, the results indicate that dietary −Cu severely impairs the ability of C58 mice to be immunized to line I_b syngeneic malignant lymphocytes (table 1), a known T-cell response (*3, 4*). Thus −Cu mice appear to have not only an impaired humoral response to sheep red blood cells (*9*) but also a definite decline in cell-mediated immunity as well. It is as yet too early to speculate which of the immunologic triad, B-cells, T-cells, or macrophages, is most affected by −Cu. Preliminary results in our laboratory indicate that the mitogen reactivity of both T- and B-cells is diminished in −Cu mice. Indeed, it appears that reactivity of T-cells from −Cu mice spleens is impaired in proportion to the plasma ceruloplasmin concentrations (Lukasewycz OA, Prohaska JR: Unpublished results). In vitro generation of cytotoxic T-cells is reduced in acute −Cu (Cu-depleted media), and this effect is most likely due to an impairment of T-cell helper function (*12*). If these findings can be extended in vivo, the loss of T-helper cell function could explain the loss of both humoral and cellular immune function seen in −Cu mice.

The exact mechanism by which immunocompetent cells and/or their subsets might be affected by Cu deprivation is unknown. One intriguing possibility is that the cytocidal function of immunocompetent cells is lowered due to −Cu. Boyne and Arthur (*13*) have shown that Cu-deprived cattle have neutrophils with decreased microbicidal activity. Whether this observation can be extended to a tumor system is yet to be determined.

−Cu leads to myriad physiologic changes, which are thought to be due to decreases in the Cu-dependent enzymes, such as ceruloplasmin, cytochrome oxidase, dopamine β-hydroxylase, lysyl oxidase, superoxide dismutase, and tyrosinase (*14*). Ceruloplasmin itself exhibits a multitude of properties (*15–17*), which include the mobilization of iron into the serum (ferroxidase), serum antioxidant activity (iron and superoxide radical scavenger), an acute-phase reactant, and Cu transport. It has recently been shown in in vitro studies with human peripheral lymphocytes that ceruloplasmin (*18*), especially in the presence of thiols (*19*), can significantly modify T-cell function. Thus the ceruloplasmin deficit seen in −Cu mice might affect the immune system directly, although the role of other cuproenzymes cannot be excluded. For example, Leuthauser et al. (*20*) have recently shown that a Cu chelate with superoxide dismutase activity has antitumor properties. Thus −Cu mice, with low superoxide dismutase activity, may be more likely to succumb to lymphocytic leukemia than those with normal enzyme levels.

The increase in ceruloplasmin evident in the C58-I_b system (text-fig. 3) is similar to the increase seen in human chronic lymphocytic leukemia (*21*) and in Hodgkin's disease (*18*). Both +Cu and −Cu mice exhibit elevated ceruloplasmin activity after I_b immunization (table 1). The rise in ceruloplasmin does not require the presence of I_b cells because Formalin-treated mice also exhibit long-term hyperceruloplasminemia (text-fig. 3). This response in −Cu mice is analogous to that seen in −Cu rats stimulated by carrageenan (*22*). The increase in ceruloplasmin is believed to be the result of its synthesis by liver due to the action of lymphocyte-activating factor released by stimulated macrophages (*23*). What the precise role of rising ceruloplasmin concentrations might be in response to tumors or as an acute-phase reactant to inflammation is yet to be determined.

Starvation experiments with the C58-I_b system performed by Martinez et al. (*8*) showed that a 2-day starvation period, bracketing the time of immunization, greatly suppresses the cellular immune response to I_b cells. Starvation also affected established immunity: Immunized mice that were starved had a significantly lower survival rate to a challenge regimen compared to that of mice that were not starved with regard to −Cu (table 1). There is, however, a considerable difference between the two systems. Starvation causes decreases in the number of peripheral blood leukocytes and in the number of nucleated splenocytes, as well as a significant reduction in spleen, thymus, and body weights (*8*). −Cu results in splenomegaly and near normal body weights (*9*). There appears to be no difference in the number of peripheral blood lymphocytes, and the number of nucleated splenocytes is increased over +Cu controls (Lukasewycz OA, Prohaska JR: Unpublished results). Adoptive cell transfer experiments showed that the immunocompetence of individual spleen immunocytes was not reduced by starvation (*8*). We are currently in the process of determining whether this is true for −Cu mouse splenocytes. This is probably not the case because of the preliminary results with in vitro mitogen assays, which indicate that the reactivity of T-cells of −Cu mice to concanavalin A is substantially below that of their +Cu counterparts.

The suppression of immunity seen here with Cu depletion also appears to be distinct from that seen with other trace element deficiencies. Zinc-deficient animals also have both an impaired humoral (*24*, *25*) and a cell-mediated (*26*) immune response, which appear to be dependent on T-helper cell function (*24*, *27*). Zinc deficiency affects cell-mediated immunity as measured by depressed T-killer cell activity against EL-4 tumors and leads to a low natural killer cell activity but essentially a normal antibody-dependent cell-mediated cytotoxicity response (*26*). However, zinc-deficient mice are characterized by an atrophic spleen and thymus, a situation that does not occur in −Cu (*9*). Furthermore, zinc metabolism is unaltered by −Cu (*28*). Lastly, many transplantable tumors show restricted growth in animals maintained on a zinc-deficient diet (*29–32*). Although the growth of those tumors has not yet been evaluated in −Cu mice, the growth of I_b cells does not appear to be slowed.

Perturbations in iron metabolism in the −Cu mice may explain both the decrease in antibody production (*9*) and the impairment of cell-mediated immunity (table 1), since iron deficiency itself can alter both humoral and cell-mediated immunity (*7*). We do not believe that iron deficiency is a major factor in the immunologic impairment seen in −Cu mice. Mice with minimal anemia and normal liver iron levels still show an impaired antibody response to sheep red blood cells (*9*). Also, a nonanemic state does not predict survival, especially in the I_b challenge of −Cu mice (table 1).

The biochemical and immunologic mechanisms in which Cu is required for a competent immune system are not known. The data herein establish that an adequate dietary level of Cu is necessary for an effective cell-mediated immune response to tumor cells.

Effects of Different Fractions of *Corynebacterium parvum* on the Cytotoxic T-Cell Response to Alloantigens in Mice[1,2,3]

Alan Lichtenstein,[4] Richard Tuttle,[5] John Cantrell,[6] *and* Jacob Zighelboim[7,8]

ABSTRACT—The effects of several biochemically derived fractions of *Corynebacterium parvum* and chemically treated intact organisms on the generation of cytotoxic T-lymphocytes (CTL) were assessed in a tumor allograft model with the use of C57BL/6 and DBA/2 mice. The acid-modified, active and inactive fragmented preparations and pyridine extract and residue were all capable of inhibiting primary spleen cell allocytotoxicity. Only the active fragmented, pyridine residue and unfractionated preparations caused splenomegaly and prevented the secondary in vitro generation of CTL. Periodate treatment, acid modification, and pyridine extraction abrogated the ability of *C. parvum* to activate suppressor macrophages. Although incapable of activating suppressor macrophages, the phenol and pyridine extracts significantly enhanced suppressor T-cell activity. The effect of whole *C. parvum* organisms on T-cell-mediated cytotoxicity is thus extremely complex and due to the direct activation or inhibition of various cell types that interact with each other.—JNCI 1982; 69:495–501.

The BRM *Corynebacterium parvum* potentiates many aspects of the immune system. It augments antibody responses (*1*), increases clearance function of the reticuloendothelial system (*2*), and activates cytotoxic macrophages (*3*). Paradoxically, it can also cause immunosuppression, inhibiting graft-versus-host reactivity (*4*), delayed cutaneous hypersensitivity (*5*), proliferative responses to mitogens and alloantigens (*6*, *7*), and cytotoxic responses to tumor-associated viral antigens and alloantigens (*8*, *9*). The paradox extends to the more recently described cytotoxicity mediated by natural killer cells, which has been reported to be amplified (*10*) as well as suppressed (*11*) by injections of *C. parvum*.

These diverse contrasting effects might be explained by an indiscriminant activation of macrophages by the drug and the subsequent interaction between these cells and other varied cell types of the immune system. Enhancement of cytotoxic or accessory macrophages as well as suppressor macrophage function could account for simultaneous positive and negative effects on the host.

An alternative explanation is that the *C. parvum* organism contains multiple determinants that independently activate different subsets of lymphoid cells with different functions. We have explored this hypothesis by examining the effects of several biochemically derived fractions of *C. parvum* and chemically treated intact organisms on the generation of T-CMC in a tumor allograft model. The depression of primary spleen cell cytotoxicity, inhibition of secondary in vitro generated CMC, and activation of suppressor cells appear to be due to separate components of the organism. In addition, several fractions were identified that activate suppressor T-cells independently of suppressor macrophage activation, whereas others activated suppressor T-cells and macrophages simultaneously.

MATERIALS AND METHODS

Animals.—Male C57BL/6 mice (The Jackson Laboratory, Bar Harbor Maine) were obtained at 6 weeks of age. They rested at least 1 week before the initiation of an experiment.

Immunization.—The P815 mastocytoma was maintained in ascites form by weekly ip passage in female DBA/2 mice (The Jackson Laboratory), the strain of origin. C57BL/6 mice were immunized on day 0 by an sc injection of 2×10^7 P815 cells. Seven days later, one group of mice received injections iv in the lateral tail vein with 0.2 ml of phosphate-buffered saline containing 500 µg of *C. parvum* (strain CN 6143; Burroughs-Wellcome Co., Research Triangle Park, N.C.) or one of its fractions. All mice were killed on day 14 for assay of spleen cell cytotoxic activity, for in vitro restimulation of splenocytes, and for the ability to suppress primary or secondary in vitro generation of CTL.

In vitro stimulations.—Spleens were removed aseptically from naive or alloimmunized mice (14 days post alloimmunization with 2×10^7 P815 sc), and a single cell suspension was prepared by filtration of the organ through a stainless-steel mesh. Spleen cells (5×10^6) were cultured with 5×10^5 mitomycin C-treated P815 in 2.5 ml of Eagle's minimum essential medium (M.A. Bioproducts, Walkersville, Md.) supplemented with 10% fetal calf serum, L-glutamine, antibiotics, and 5×10^{-5} *M* 2-mercaptoethanol. The cultures were maintained at 37°C for 5 days in a humidified CO$_2$ incubator, after which the cells remaining in culture were harvested and tested for cytotoxic activity. To test for suppressor cell activity, we added 5×10^6 spleen cells from *C. parvum*- or fraction-treated alloimmunized mice to 5×10^6

ABBREVIATIONS USED: ATS=antithymocyte serum; BRM=biologic response modifier(s); C=complement; CMC=cell-mediated cytotoxicity; CTL=cytotoxic T-lymphocyte(s); E:T=effector-to-target cell ratio(s); T-CMC=T-cell CMC.

spleen cells from alloimmunized control (secondary stimulation) or naive control (primary stimulation) animals prior to the initiation of culture. Addition of spleen cells from naive or alloimmunized mice had no significant effect on the specific cytotoxic activity of stimulated cells. As we have previously reported (*12*), addition of spleen cells from naive mice given iv injections of 700 μg *C. parvum* up to 7 days prior to assay has no effect on in vitro CTL generation, although spleen cells from naive mice given injections of 1,400 μg are significantly suppressive to CTL generation.

Test for CMC.—Spleen cells taken directly from mice or harvested from 5-day cultures were tested for cytotoxic activity against ^{51}Cr-labeled P815 by the method of Brunner et al. (*13*). Cytotoxicity was measured at several E:T with the use of an incubation period of 4 hours. Results are expressed as percent specific release calculated as follows: Percent specific release = [(percent release experimental group − percent minimum release)/percent maximum release] × 100. Maximum release was determined by addition of concentrated HCl to a final dilution of 1 *M* and was generally between 80 and 90% of total incorporated counts. Minimum release was a medium control and ranged from 7 to 15% of total incorporated counts. One lytic unit was defined as the number of effector cells required to yield 25% specific release in primary cultures and primary in vivo spleen cytotoxicity and 50% specific release in secondary cultures.

Fractionation of C. parvum.—The fractions investigated in this study are listed in table 1 with their composition if known.

Phenol-water extraction.—Killed *C. parvum* was extracted with hot phenol-water (1:1) by the standard Westphal method as previously described (*14*). Material extracted in the phenol phase was designated the "phenol extract" (fraction A). The pelleted residue material was resuspended and centrifuged at 30×*g* for 10 minutes, and the supernatant was obtained and designated the "light residue" (fraction B). We have previously reported on some of the effects of the phenol extract and light residue on T-CMC (*15*).

Disruption.—The active fragmented fraction C was supplied by Dr. V. Riveros-Moreno, Burroughs-Wellcome Ltd., Beckenham, England. The fraction was prepared by disruption in an X-press in the presence of 20 m*M* dithiothreitol as previously described (*16*). The preparation was lyophilized and stored. Some of its properties have been previously reported (*17*).

TABLE 1.—*Composition of* C. parvum *fractions*[a]

Fraction	Percent of recovered material	Percent of fraction by weight		
		Protein	Fatty acid	Total sugar
Whole cells	—	29.2	36.2	11.8
A: Phenol extract	9	40.5	39.6	2.3
B: Light residue	88	26.6	31.2	10.5
C: Active fragmented	NT	NT	NT	NT
D: Inactive fragmented	NT	2.5	NT	14.5
E: Pyridine extract	9	12.1	47.2	12.4
F: Pyridine residue	91	21.4	33.6	12.2
G: Periodate modified	NT	NT	NT	NT
H: HCl modified	NT	NT	NT	NT

[a] NT=not tested.

The inactive fragmented preparation (fraction D) was also a gift of Dr. V. Riveros-Moreno and prepared as described by Riveros-Moreno et al. in (*18*). Whole bacteria were broken in a Novotny cell disruptor. After the cells were resuspended in 0.1 *M* Tris buffer (pH 7.6), Ballotini beads (#12) were added, and the mixture was prepared at 10,000 rpm for 1.5 minutes on ice and NaCl in a homogenizer. The homogenate was filtered and the glass beads were washed. The material was centrifuged at 1,000×*g* for 20 minutes at 4°C, and the resulting supernatant was treated sequentially with 2% sodium dodecyl sulfate, trypsin, DNase, and RNase as previously described (*18*). Some of the properties of this preparation have been previously reported (*18*).

Pyridine extraction.—Ninety grams (wet weight) of washed *C. parvum* whole-cell paste was added to 200 ml of neat pyridine, reagent grade (J. T. Baker Chemical Co., Phillipsburg, N.J.). The extraction mixture was stirred for 18 hours at 37°C. Supernatant fraction obtained after centrifugation of the mixture at 17,000×*g* for 1 hour at 4°C was designated the "pyridine extract" (fraction E). Pelleted materials were extracted two times more in the original volume of pyridine. After filtration, the pyridine soluble extracts were pooled and the solvent was removed by evaporation at 50°C in a Buchi Rotavapor (Brinkmann Instruments, Inc., Westbury, N.Y.). The dried pyridine extract was dialyzed against distilled water, freeze dried, and lyophilized. The insoluble residue (fraction F) was washed three times with sterile, distilled water. After centrifugation at 17,000×*g* for 1 hour at 4°C, the residue was suspended in distilled water, dialyzed for 7 days, and then lyophilized.

Periodate and HCl modifications.—Periodate and HCl modifications of whole organisms were performed as previously described (*19*). Organisms suspended in phosphate-buffered saline were mixed with sodium metaperiodate (pH 5.0) and held in the dark for 30 seconds. The final molarity of periodate was 250 m*M*. The action of the oxidant was stopped by addition of 20% glucose solution. This preparation (fraction G) and its effect on spleen weight have been previously reported (*19*). Lyophilized organisms were suspended in 0.1 *N* HCl in a stoppered tube and held in a temperature-controlled water bath for 10 minutes. This preparation (fraction H) and its effect on spleen weight have been previously reported (*19*).

Fractionation of suppressor cells.—Phagocytic cells were removed by incubation of spleen cells with carbonyl iron (GAF Corp., New York, N.Y.) for 30 minutes at 37°C followed by separation over a magnet. Recovery was between 40 and 60% of starting cell numbers. This treatment reduced the percentage of nonspecific esterase-positive cells in spleens from *C. parvum*-treated mice from 20 to 25% to less than 1%.

T-cells were removed by incubation of 10^7 cells/ml in a 1:45 dilution of absorbed rabbit anti-mouse thymocyte serum (M.A. Bioproducts) for 30 minutes at 4°C. The cells were centrifuged and incubated at the same concentration in a 1:15 dilution of agarose-absorbed guinea pig C (M.A. Bioproducts) for 30 minutes at 37°C. This concentration killed 100% of thymocytes, less than 10% of bone marrow cells, and 40–50% of spleen cells. The treatment also abrogated the proliferative response to the T-cell mitogen phytohemagglutinin. The cells were washed and resuspended at the desired concentration of viable cells.

Statistics.—The *t*-test was utilized to determine *P*-values between experimental and control groups.

RESULTS

Effect of iv injection of C. parvum *fractions on generation of primary T-CMC in spleen.*—Administration of iv *C. parvum* to alloimmunized mice depresses the subsequent generation of alloreactive splenic CTL (*20*). We investigated whether several biochemically derived fractions of active organisms or chemically treated intact organisms can also mediate this inhibition of CMC. Mice were alloimmunized and given injections of 500 μg of various *C. parvum* fractions on day 7. (Immunized mice not given injections served as the control group.) Fourteen days after alloimmunization (day +14), mice were killed and spleen cells assayed for cytotoxicity to allogeneic tumor cells. Table 2 demonstrates that unfractionated *C. parvum*, as well as the active fragmented fraction, markedly depresses the generation of cytotoxic splenocytes. In addition, the HCl-modified preparation, pyridine extract, and pyridine residue were all capable of depressing primary splenic CMC. The periodate-modified fraction had a minimal effect on cytotoxicity. A somewhat surprising finding was that the inactive fragmented fraction caused significant depression of splenic CMC.

Induction of splenomegaly by C. parvum *fractions.*—Table 3 demonstrates that the depressive effects of the various fractions on spleen CMC were not simply due to induction of splenomegaly and dilution of CTL by influx of irrelevant cells. Spleen cell indices were measured in alloimmunized mice at the time of assay 7 days after fractions were injected (500 μg). Only the unfractionated organism, the active fragmented preparation, and the pyridine residue clearly induced splenomegaly.

Effect of C. parvum *fractions on secondary in vitro generation of CMC.*—Administration of *C. parvum* to alloimmunized mice prevents the subsequent generation of secondary CTL following rechallenge in vivo and in vitro (*9, 21*). Table 4 shows the effects of the different fractions on the generation of secondary CTL in vitro. Alloimmunized mice were either not given injections (control group) or given injections of 500 μg of various fractions 7 days after alloimmunization. On day +14, mice were killed and spleen cells were restimulated for 5 days in vitro with allogeneic tumor cells. As shown, only unfractionated *C. parvum*, the active fragmented preparation, and the pyridine residue were effective in inhibiting the subsequent generation of secondary CTL in vitro.

TABLE 2.—*Effect of* C. parvum *fractions on generation of primary splenic allocytotoxicity*[a]

Agent injected	Percent specific release at E:T		
	100:1	20:1	4:1
Control	27±5	13±3	5±1
Whole *C. parvum*	2±.4[b]	1±.2[b]	1±.3[b]
Fraction C: Active fragmented	3±1[b]	2±.6[b]	1±.5[b]
Fraction D: Inactive fragmented	7±1[b]	5±.4[b]	1±.4[b]
Fraction H: HCl modified	10±3[b]	6±1.1[b]	2±.6[b]
Fraction G: Periodate modified	19±6	8±4	3.5±1

Fraction F: Pyridine residue	5±2[b]	3±1[b]	1±.2[b]

[a] Primary spleen cytotoxicity was assayed in a ^{51}Cr release assay against chromated P815 cells 14 days after alloimmunization and 7 days after injection of whole or fractionated *C. parvum* organisms (500 μg). Results are mean percentages of specific lysis ± SD of three experiments (2–3 mice/each group/each individual expt). Lysis was determined at three E:T.

[b] Significantly different from control, $P<0.05$.

TABLE 3.—*Effects of* C. parvum *fractions on splenic cellularity*[a]

Agent injected	Spleen cell index
Whole *C. parvum*	2.54±0.29
Fraction C: Active fragmented	2.18±0.21
Fraction D: Inactive fragmented	1.13±0.09
Fraction H: HCl modified	1.11±0.11
Fraction G: Periodate modified	1.34±0.14
Fraction E: Pyridine extract	1.30±0.13
Fraction F: Pyridine residue	2.10±0.24

[a] Splenic cellularity was determined 14 days after alloimmunization and 7 days after injection of whole or unfractionated *C. parvum* organisms (500 μg). Spleen cell index was calculated by the following formula: (Cellularity/spleen of whole or fraction treated mice)/(cellularity/spleen of control mice). Results are means ± SD of four experiments (2–3 mice/group/expt).

TABLE 4.—*Effect of* C. parvum *fractions on generation of secondary in vitro CMC*[a]

Agent injected	Percent specific release at E:T		
	25:1	5:1	1:1
Control	83±4	70±6	41±3
Whole *C. parvum*	10±2[b]	2±1[b]	1±.4[b]
Fraction C: Active fragmented	19±3[b]	6±1[b]	3±1[b]

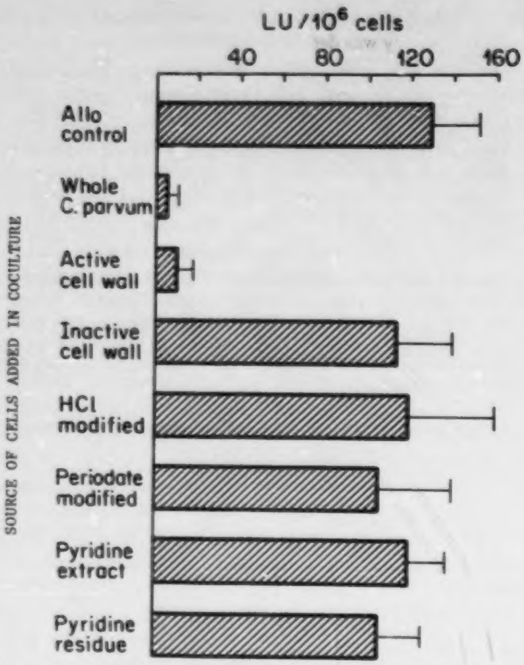
Fraction F: Pyridine residue	58±3[b]	15±3[b]	3±1[b]

[a] Alloimmune control or alloimmunized mice that received iv injections of whole or fractionated *C. parvum* were killed 14 days after immunization (2×10^7 P815 cells), and spleen cells were restimulated with P815 for 5 days after which secondary CTL generation was assayed against chromated P815 targets. Results are mean percentages of specific lysis ± SD of three experiments (2–3 mice/each group/each expt). Lysis was determined at three E:T.

[b] Significantly different from control, $P<0.05$.

Activation of suppressor cells.—We have previously reported that *C. parvum* activates suppressor macrophages and T-cells (*12*). The former markedly curtail primary and secondary in vitro generation of CTL, whereas the latter are only effective in preventing primary in vitro CMC. Text-figure 1 demonstrates the ability of spleen cells from fraction-treated alloimmune mice to suppress the generation of secondary CTL in vitro. The active fragmented preparation is as effective as the whole organism in this regard. In contrast, periodate modification, HCl modification, and pyridine extraction alter the organism so that it no longer activates suppressor macrophages.



TEXT-FIGURE 1.—Activation of suppressor cells that curtail in vitro generation of secondary CTL by various *C. parvum* fractions. Suppressor spleen cells were obtained 7 days after injection of whole or fractionated *C. parvum* (14 days after alloimmunization) and added to spleen cells from alloimmune control (Allo control) mice (14 days after alloimmunization). These cocultures were restimulated with mitomycin C-treated P815 for 5 days, and the generation of secondary CTL was assessed against P815 targets. Addition of equivalent numbers of spleen cells from alloimmune control mice to secondary cultures resulted in cytotoxicity identical to that generated in secondary cultures alone, and this control is not shown. Results are lytic units (LU)/10^6 cells generated in culture, mean ± SD of four experiments. Active cell wall=active fragmented fraction C; inactive cell wall=inactive fragmented fraction D.

TABLE 5.—*Activation of either suppressor macrophages or T-cells by* C. parvum *fractions*[a]

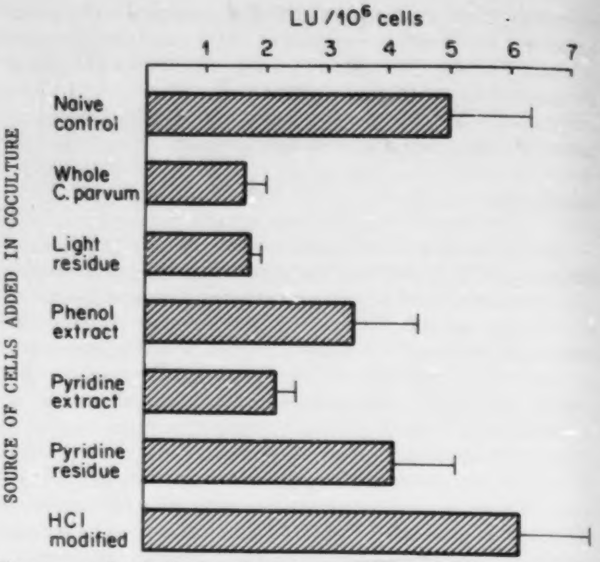
Light residue injected	Iron and magnet	1.7±0.2[b]
Light residue injected	ATS and C	1.6±0.2[b]
Light residue injected	Iron and magnet–ATS and C	4.5±1.1

[a] Putative suppressor spleen cells from whole *C. parvum*- or light residue-treated alloimmunized mice were added to primary sensitizations or first fractionated to remove phagocytic or theta-bearing cells before addition to primary cultures. After 5 days of culture, cytotoxicity to chromated P815 targets (the stimulating cells) was assessed. Results are mean lytic units/10^6 cells in culture ± SD of three experiments.

[b] Significantly different from control, $P<0.05$.



TEXT-FIGURE 2.—Activation of suppressor cells that curtail in vitro generation of primary CTL by various *C. parvum* fractions. Suppressor spleen cells were obtained 7 days after injection of whole or fractionated *C. parvum* (14 days after alloimmunization) and added to spleen cells from naive mice. These cocultures were stimulated with mitomycin C-treated P815 for 5 days, and the generation of primary CTL was assessed against P815 targets. Suppressor cells were treated with mitomycin C before addition to culture for prevention of their clonal expansion when encountering P815, the alloantigen to which they had been primed. Addition of mitomycin C-treated alloimmune control splenocytes to primary cultures resulted in cytotoxicity identical to that generated in primary cultures alone, and this control is not shown. Results are lytic units (LU)/10^6 cells generated in culture, mean ± SD of four experiments.

[a] Putative suppressor spleen cells from phenol- or pyridine extract-treated alloimmunized mice were added to primary sensitizations or first fractionated to remove phagocytic or theta-bearing cells before addition to primary cultures. After 5 days of culture, cytotoxicity to chromated P815 targets (the stimulating cells) was assessed. Results are mean lytic units/10^6 cells in culture ± SD of three experiments.

[b] Significantly different from control, $P<0.05$.

The fractions were also assayed for their ability to activate suppressor cells that prevent primary in vitro CMC. Text-figure 2 demonstrates that unfractionated *C. parvum*, light residue (obtained after phenol–water extraction), and the pyridine extract significantly activate suppressor cells that prevent the generation of primary CMC. The phenol extract modestly activates suppressor cells, whereas HCl-modified and pyridine residue fractions are without effect.

Prior to the addition of putative suppressor cells to primary cultures, suppressor cells were depleted of T-cells by treatment with ATS and C or of macrophages by incubation with iron fillings and exposure to a magnet. Although depletion of T-cells and macrophages independently had no effect on suppression mediated by spleen cells from mice treated with whole *C. parvum* or light residue, suppression was abrogated when the spleens were depleted of T-cells and macrophages by sequential use of both fractionation procedures (table 5). We have interpreted these results to indicate the simultaneous activation of suppressor T-cells and macrophages. In contrast, suppression of primary CMC mediated by spleen cells from mice given injections of phenol and pyridine extracts is completely abrogated by treatment with ATS and C, indicating the sole activation of suppressor T-cells (table 6).

DISCUSSION

The results of the current study confirm and extend our previous observations utilizing different fractions of *C. parvum* (*15*) in regard to several points. First, the inhibition of T-CMC by *C. parvum* appears to be due to the effects of several biochemical moieties of the organism that function independently to modulate various aspects of T-CMC. Acid modification and pyridine extraction yield preparations that have lost the ability to inhibit secondary CMC but effectively curtail primary spleen cytotoxicity, indicating the distinctness of the structures that induce these effects. These results also indicate that, under certain ,conditions, the generation of primary allocytotoxic T-lymphocytes can be completely dissociated from the expression of secondary CMC.

Second, while the pyridine residue administered in vivo to immunized mice markedly inhibited in vitro secondary CMC generation, it did not generate cells that suppressed secondary stimulation in coculture experiments. Thus *C. parvum* appears to inhibit secondary CMC by at least two mechanisms: the activation of suppressor cells and a second effect that is possibly exerted on the priming process. Alternatively, this second mechanism may simply be a dilution of secondary CTL precursors by a marked influx of irrelevant cells into the spleen, because only the fractions capable of inducing splenomegaly could inhibit the restimulation in vitro.

The action of the various distinct *C. parvum* determinants may be exerted on different cell types of the immune system to account for the diversity of effects. One possible hypothesis is that each determinant activates a specific macrophage subpopulation with a predetermined function. The report by Lee and Berry (*22*) on the physical separation of accessory and suppressor–cytotoxic macrophages activated by *C. parvum* is consistent with this concept. Furthermore, Scott and Warner (*23*) described the activation of macrophages cytostatic for tumor cells by low doses of *C. parvum* without the accompanying activation of macrophages suppressive for T-cell responses, which suggests that the threshold dose for activation of different macrophage subsets may vary. Our results also support the activation of different subsets of macrophages by *C. parvum*. Although the pyridine extract has been reported to activate cytotoxic macrophages (*24*), we found it incapable of activating suppressor macrophages. In a similar fashion, the periodate-treated residue fraction obtained from phenol–water extraction has been reported to activate peritoneal cytotoxic macrophages (*14*), although it (*15*) and the periodate-modified whole-cell preparation used in the current study could not activate suppressor macrophages.

Although *C. parvum* is best known for its macrophage-activating properties, some of its multiple effects may also be due to stimulation of other cell types by other determinants. In this regard, the induction of suppressor T-cells by the phenol extract and the pyridine extract suggests that some components of the *C. parvum* organism can directly activate subsets of T-cells. We had previously noted an inhibition of C-dependent cytotoxic antibody titers caused by administration of the phenol extract to alloimmunized mice, whereas other fractions derived from phenol–water extraction had no effect on the antibody response (*15*). It is tempting to relate this inhibition of alloantibody response to the induction of suppressor T-cells by the phenol extract.

The effects of *C. parvum* fractionation on the ability of the agent to modulate CMC provide some insight into the nature of the determinants responsible for this phenomenon. The active fragmented preparation was comparable to unfractionated *C. parvum* in its inhibition of primary and secondary CMC and activation of suppressor cells, suggesting that at least some of the relevant inhibitory determinants are located in the cell wall structure. In contrast, the inactive fragmented preparation was incapable of inhibiting secondary CMC or activating suppressor cells. Like most other cell wall preparations, the inactive fragmented fraction does not induce splenomegaly (*18*), whereas the active fragmented preparation is an unusual one in that it does induce splenomegaly (*17*). The active one is prepared by fracturing the organism in the presence of the reducing agent dithiothreitol, which may have allowed preservation of the ability to modulate CMC as well as to induce splenomegaly.

In contrast, administration of the inactive fragmented fraction significantly inhibited the generation of primary spleen cytotoxicity. Apparently, the requirements for inhibiting this cytotoxic function are less restricted because most of the fractions tested significantly inhibited the development of primary CMC. In preliminary experiments, a related organism that did not induce splenomegaly (*Corynebacterium granulosum*, CN5888; Burroughs-Wellcome Co.) was capable of inhibiting the generation of primary CMC. This phenomenon raises the question of whether this inhibition is a biologic activity that is unique to the "active" (reticuloendothelial system-stimulating) strains of *Propionibacterium*. Alternatively, these "inactive" preparations may be inactive only insofar as induction of splenomegaly is concerned. In fact, inactive *C. granulosum* is capable of producing chemotactic factors for macrophages (*25*) and can significantly reduce the incidence of tumor nodules in the lung (*26*) although less effectively than does unfractionated *C. parvum*. Although splenomegaly has historically been used as an indicator of biologic activity, these and other data suggest that the activity of a preparation must be defined by the assay used. To further investigate this question, we are devising experiments to assess whether inhibition of primary CMC can be mediated by injection of unrelated organisms or inert particles.

Periodate treatment and HCl treatment of whole organisms abrogate the ability of the adjuvant to inhibit the development of secondary CMC and to activate suppressor macrophages. Although these preparations have not yet been assayed biochemically, both these procedures are reported to markedly liberate galactose residues (*14*, *27*), which suggests that these carbohydrates are important in inducing these effects on the immune system. Since the HCl-modified fraction effectively inhibits primary spleen cytotoxicity, galactose residues are probably not critical in that immunosuppressive action. Neither are galactose residues important in inducing splenomegaly, since *Propionibacterium* species type II can induce splenomegaly and does not contain galactose (*28*). Assaying type II species for their ability to inhibit secondary CMC and to activate suppressor cells will assist in supporting or refuting the hypothesis that galactose residues are prerequisites for these effects.

A dose of 500 μg/mouse was selected for this study because previous experiments indicated that the effects of whole *C. parvum* on T-CMC were lost when a dose of less than 70 μg was used (*29*), and we have seen significant mortality (50–75% of mice) when doses greater than 1,000 μg are administered iv. Comparing fractions at a standard dose (500 μg/mouse) allowed for the detection of significant biologic effects of certain fractions that are present in minimal quantities in unfractionated organisms (i.e., phenol- and pyridine-extractable fractions). However, since extensive dose-response curves for all the fractions have not been completed, it is unclear whether the above active fractions contribute to the overall effects following administration of whole *C. parvum*. Since these active fractions consist of approximately only 10% of recovered material (table 1), injection of 500 μg of purified material is a great enrichment compared to equivalent doses of unfractionated *C. parvum*.

Several laboratories are now actively producing and assessing fractions of *C. parvum* organisms. Simpler preparations with more selective effects on immune and antitumor responses theoretically provide better BRM for use in immunotherapy of cancer. Brunda et al. (*30*) have shown that the inhibitory and stimulating effects of *C. parvum* on natural killer cytotoxicity reside on separate components of the organism. We have also identified fractions that appear to be enriched for the determinants enhancing natural killer cytotoxicity and others that lack these determinants (*31*). A prime candidate for antitumor therapy would be the pyridine extract, which has antitumor activity in animal models (*24*), stimulates natural killer cytotoxicity (*31*) in rats following ip injection, and has no effect on secondary CMC and is not capable of activating suppressor cells.

A secondary important use for these fractions is as probes for the study of the cellular interactions of normal immune responses. A good example of this is our own model for enhancing suppressor cell activity. While this model allows for interesting comparisons between the effects of suppressor T-cells and macrophages induced within the same animal by the same conditions, it is cumbersome when one is attempting to isolate and to study only one suppressor cell type. The availability of fractions (phenol and pyridine extract) that can selectively activate suppressor T-cells is an important tool for the continued study of these cells within this system.

Chemical Cocarcinogenesis With the Use of a Subclone Derived From Balb/3T3 Cells With Catechol as Cocarcinogen[1,2]

Mahalakshmi Atchison,[3] **Ching-shan Chu,**[4] **Takeo Kakunaga,**[5] *and* **Benjamin L. Van Duuren**[3,6]

ABSTRACT—This study was performed for the detection of cocarcinogens by transformation in vitro with the use of a subclone of a Balb/3T3 cell line. Dose response, cytotoxicity, and transformation studies were done with the use of an indirect-acting carcinogen, benzo[*a*]pyrene (B[*a*]P), a direct-acting alkylating carcinogen, β-propiolactone (BPL), and the mouse skin cocarcinogen catechol. The rate of transformation was notably higher in groups treated with B[*a*]P and catechol or BPL and catechol than in groups treated with either B[*a*]P or BPL. Catechol alone did not induce any transformation. All the cells isolated from the transformed foci showed characteristics of malignantly transformed cells, such as anchorage-independent growth. Thus chemical cocarcinogenesis was accomplished in vitro similar to that accomplished in in vivo studies reported earlier on mouse skin.—JNCI 1982; 69:503–508.

A series of compounds shows the effect of enhancing significantly the incidence of benign and malignant tumors induced by B[*a*]P on mouse skin when the carcinogen B[*a*]P and cocarcinogen are applied simultaneously and repeatedly (*1–4*). These compounds are not carcinogenic, and most of them are not tumor-promoting agents in the classical two-stage carcinogenesis experiment, i.e., initiation–promotion on mouse skin (*4*). They are referred to as cocarcinogens. There is, therefore, a clear-cut operational difference in the two types of experiments. Not all cocarcinogens are tumor promoters and *vice versa*. These definitions are those of Berenblum (*1*), and they have also been used in our earlier work (*4*). Cocarcinogens for mouse skin belong to various classes of chemicals including polyphenols, aromatic hydrocarbons, long-chain aliphatic hydrocarbons, and others, and hence they probably act by different mechanisms (*4, 5*).

To extend the possibilities for studies on the mechanism of action of cocarcinogens, we undertook the present study to develop a cell culture system for cocarcinogenesis.

The cells selected for the present work are the A31-1-1 subclone isolated from clone A31-1 of Balb/3T3 cells (*6*). These early-passage cells, 50 generations, exhibit a high degree of contact inhibition, homogeneous cell morphology, and a low incidence of spontaneous transformation. Malignant transformation has been observed with the use of these cells treated with several carcinogens, e.g., 4-nitroquinoline-*N*-oxide (*7*).

Catechol, a potent mouse skin cocarcinogen (*4*), occurs in plants (*8, 9*), is manufactured and used in diverse industries (*9*), and is the major phenolic component in cigarette smoke condensate (*10*). In a recent study catechol was shown to be the major cocarcinogen in a subfraction of cigarette smoke condensate on the basis of mouse skin bioassays with the use of B[*a*]P as carcinogen (*11*). It is not carcinogenic by skin application in mice (*4*) and is not a promoter in two-stage carcinogenesis on mouse skin (*4*). It was used in the present work with two carcinogens in separate in vitro cocarcinogenesis experiments: B[*a*]P, an indirect-acting carcinogen, and BPL, a direct-acting alkylating carcinogen.

MATERIALS AND METHODS

Cells.—A subclone, A31-1-1, derived from Balb/3T3 cells and described earlier (*6, 7, 12–14*), was used for all the experiments. For all the experiments, cells were cultured in 60-mm plastic petri dishes (Falcon Plastics, Oxnard, Calif.). Stock cultures were maintained in plastic tissue culture flasks (75 cm^2; Falcon Plastics). The complete medium used in all experiments and in stock cultures was EMEM (GIBCO, Grand Island, N. Y.) containing 100 U penicillin, 100 μg streptomycin, and 0.25 μg amphotericin B/ml (GIBCO) and supplemented with 10% FCS from Biofluids Inc., Rockville, Md. All washing procedures were done in HBSS (GIBCO) containing 400 U penicillin, 400 μg streptomycin, and 1.0 μg amphotericin B/ml. The cultures were incubated in a humidified incubator at 37°C in an atmosphere of 5% CO_2 in air. The media were changed two or three times a week. Passage of cultures was performed with the use of 0.25% trypsin (GIBCO).

Chemicals.—B[*a*]P, BPL, and catechol were purified and characterized as described before (*4, 15*). Solutions of the test compounds B[*a*]P and catechol were prepared in amber containers. The compounds were dissolved in acetone and diluted with complete medium at 37°C for preparation of appropriate stock solutions. The compounds were further diluted in complete medium so that the required dose would be obtained in a final concentration of 0.1% acetone. Control

cultures received only 0.1% acetone, which was nontoxic at this concentration. Stock solutions of BPL were freshly prepared, 1.14 mg/ml of culture medium, and the experimental solutions were then prepared immediately before use by serial dilution of the stock solution with the culture medium to give the final desired concentrations. All the experimental solutions of the compounds were freshly prepared, and the carcinogen plus cocarcinogen solutions in medium were then made up in one solution so that they were applied simultaneously to cultures.

Cytotoxicity, cloning efficiency, and transformation.—Cells obtained from freshly confluent stock flasks were seeded at 5×10^2 cells/60-mm petri dish for cytotoxicity assays and at 1×10^3 cells/60-mm petri dish for transformation assays 24 hours before chemical treatment. Each experiment was divided into 8 groups, 10 dishes per group. B[*a*]P was used at 0.02, 0.01, and 0.005 μg/ml; catechol was used at 2.0, 1.0, and 0.5 μg/ml; there were six experiments in which B[*a*]P and catechol were used in combination as given under "Results." In addition, B[*a*]P and catechol each were examined alone at all the above doses in the control experiments. Other controls were the medium control and an acetone control. Similar protocols were used for cotransformation studies with the use of simultaneous exposure of BPL and catechol. The concentrations of BPL were 4, 2, 1, and 0.5 μg/ml, and the concentration of catechol was 1 μg/ml with 10 dishes per group. In a reverse experiment the concentrations of catechol were 2.0, 1.0, and 0.5 μg/ml, respectively, and the concentration of BPL was 1.0 μg/ml. Cells were exposed to carcinogen and cocarcinogen as described above for 72 hours in 6 ml of medium per dish. Thereafter, they were washed twice with HBSS and maintained in the culture medium alone. Medium was changed twice weekly. At the end of the experiment, the dishes were washed twice with HBSS, fixed with methanol, and stained with Giemsa at 8 days for CE studies and at 23–26 days for transformation assays. The CE is defined as the number of colonies formed as a percentage of the number of cells seeded. The RCE is expressed as the number of colonies in the treated cultures as a percentage of those in the untreated cultures and acetone controls. Morphologic transformation was defined as an increase in cell density accompanied by numerous cells growing on the surface of the cell sheet forming foci with a loss of polar orientation of the cells on the background monolayer as shown in figure 1 (*12–14*). This was used as the criterion of the transformed phenotype. Such transformed areas were collected by the ring-isolation technique (*16*) for growth in soft agar and subsequently in culture.

Growth in soft agar.—The procedure used was described earlier (*17*). The cell suspension was mixed with agar (Difco Laboratories, Detroit, Mich.) at 44°C and diluted with agar to a final concentration of about 1×10^5 cells/dish in 0.3% agar. This suspension of cells in agar was layered over 5 ml of 0.5% agar base layer prepared in double-strength synthetic medium supplemented with 20% FCS in 60-mm dishes. The dishes were incubated in an atmosphere of 5% CO_2 in air. A total of 51 dishes, three dishes per group, were seeded with cells in agar. The dishes were held for 40 days to score for colonies larger than 1 mm. Such colonies were isolated from each group of dishes and were grown in 75-cm^2 flasks to raise the stock cells of transformed line and were stored in liquid nitrogen for future use and characterization.

RESULTS

To determine the dosage of the three test chemicals to be used in the transformation assays, we first obtained CE_{50} values (*18*). The CE_{50} values for B[*a*]P, BPL, and catechol (in μg/ml of medium) were 0.015, 3.60, and 1.0, respectively. The nontoxic doses were 0.005, 1.0, and 0.5 μg/ml of medium for the three chemicals, respectively. The highest doses used were 0.02, 4.0, and 2.0 μg/ml for B[*a*]P, BPL, and catechol, respectively. Concentrations slightly above the maximum values given above rapidly resulted in complete cell lethality. The doses used in the transformation assays were based on the CE_{50} values. The CE of the 0.1% acetone control was 42.53%, and this concentration of acetone gave the same CE as control cultures without acetone.

The detailed results of the transformation experiments with the use of B[*a*]P and catechol are given in table 1. The number of cells plated for the transformation experiments was 10^3/dish; this cell number was optimal for all of our transformation experiments with the use of this early-passage subclone. Cells treated with catechol alone did not produce any transformed foci. B[*a*]P alone at 0.02, 0.01, and 0.005 μg/ml induced the same average number of transformed foci per dish, i.e., 0.5. Simultaneous treatment of cells with the above concentrations of B[*a*]P plus 1 μg catechol/ml for each dose of B[*a*]P gave 4.4-, 2.6-, and 5.2-

4.0	1.0	23.7	3.5±0.51	34.7	<0.1

[a] 5×10^2 cells/60-mm dish for RCE; 1×10^3 cells for transformation assays. Dishes for RCE were fixed and stained 8 days after plating; dishes for transformation were fixed and stained 21 days after plating.

[b] Average number ± SD from 10 plates. ND=not determined.

[c] Statistically compared with the group of BPL-alone treatment on the basis of number of foci per dish with the use of a two-sample *t*-test. When transformation frequencies were used for calculation, statistical significance was larger. —=statistical calculation not significant or not needed.

fold increases, respectively, compared to the increases seen with B[*a*]P alone. The transformation frequency was highest at the lowest dose of B[*a*]P with 1 μg catechol/ml.

Treatment of cells with various concentrations of catechol, 2, 1, and 0.5 μg/ml, with 0.01 μg B[*a*]P/ml gave 4.6-, 2.4-, and 1.0-fold increases in B[*a*]P transformation, respectively, compared to the increases seen in cultures treated with B[*a*]P alone. The rate of transformation was linear up to 2 μg catechol/ml added. All experiments with B[*a*]P at the above three doses (0.02, 0.01, and 0.005 μg/ml) in combination with catechol at 1.0 or 2.0 μg/ml resulted in increased transformation levels over those seen with B[*a*]P alone at $P<0.05$ with the use of a two-sample *t*-test. When catechol was used at 0.5 μg/ml with B[*a*]P at 0.01 μg/ml, no increase in transformation was seen.

The data on the transformation frequency of BPL alone and BPL together with catechol are summarized in table 2. Cells treated with BPL alone at 4, 2, and 1.0 μg/ml gave 2.8, 0.75, and 0.4 foci/dish, respectively; i.e., there was a linear increase in transformation frequency with increased BPL concentration. When the same BPL concentrations were used simultaneously with 1 μg catechol/ml, the transformation frequency increased by 1.25, 6.0, and 5.0 times when compared to that of cultures treated with BPL alone. The frequency of transformation was highest at 2 μg BPL/ml together with 1 μg catechol/ml added and the transformation frequency decreased slightly at 4 μg BPL/ml with 1 μg catechol/ml. This decrease may be due to the combined toxic effects of the compounds on cells.

When cells were isolated from individual transformed foci, all produced populations of typical transformed cells in culture and demonstrated a loss of contact inhibition and oriented growth. They subsequently gave rise to colonies of anchorage-independent cells (fig. 2), whereas the control cultures did not. Dense, multilayer areas of untransformed cells isolated from treated or control cultures also failed to produce colonies in soft agar. A transformed line was isolated from the colonies that developed in soft agar from transformed foci treated with B[*a*]P (0.005 μg/ml) and catechol (1 μg/ml) 23 days after cell seeding. This cell line (TCL3a) is shown in figure 3.

DISCUSSION

Cocarcinogenesis in vivo has been established in various laboratories (*1–5*). Many of these studies have focused on mouse skin experiments (*1*, *2*, *4*). Because of the range of chemical structural types that exhibit cocarcinogenicity, it appears unlikely that all these compounds affect the target organ in the same way. This is supported by a recently reported study of the effects of five chemicals that enhance mixed-function oxidase activity in vivo (*19*). When tested in an in vitro mouse embryo fibroblast system, C3H10T$\frac{1}{2}$/-CL8, with B[*a*]P as carcinogen, four of the five agents enhanced B[*a*]P-induced transformation; the exception was Aroclor 1254, a well-known inducer of mixed-function oxygenases in mouse liver (*20*). These findings suggest, as the authors point out (*19*), that certain metabolic pathways and the pharmacokinetics that are operative in vivo do not necessarily occur in vitro. Another recent report describing the effect of B[*e*]P on B[*a*]P metabolites showed that the relative proportions of B[*a*]P metabolites formed in hamster embryo cells are altered in the presence of B[*e*]P (*21*). A third in vitro cocarcinogenesis report concerns the effect of B[*e*]P on B[*a*]P carcinogenesis in respiratory tract mucosa in organ culture (*22*). B[*e*]P, a mouse skin cocarcinogen, was not cocarcinogenic for respiratory tract carcinoma induction in organ culture but did enhance tracheal and peritracheal sarcomas twofold to threefold in the same experiments.

With these complications in mind, it is still highly desirable to perform cocarcinogenesis studies in vitro. The in vitro system provides the obvious advantage of one cell type, for which some of the biochemical and biological characteristics have been described before.

Because catechol did not show tumor-promoting activity on mouse skin (*4*), it was not tested in the present in vitro system for tumor-promoting activity.

The results presented in this report clearly demonstrate the cocarcinogenic activity of catechol on B[*a*]P- as well as BPL-induced transformation in vitro. This system is potentially useful for the study of mechanisms of action of mouse skin cocarcinogens in vitro. It may also develop to be an in vitro screen for other potential cocarcinogenic agents, once a larger number of mouse skin cocarcinogens have been successfully tested in vitro as cocarcinogens.

In an earlier report we have enumerated several possible modes of action of cocarcinogens (*5*). The present findings suggest that the effect of catechol may involve an interference with repair of DNA damaged by the direct-acting carcinogen BPL in which alteration in metabolic pathways is not involved; the latter effect can occur with B[*a*]P as carcinogen.

Immunotherapy of a Murine Leukemia Virus-Infected, Chemically Induced Murine Sarcoma With Antiviral Antibodies[1,2,3]

Edward C. Ward,[4,5,6] **J. Dirk Iglehart,**[7] **Kent J. Weinhold,**[7] *and* **Dani P. Bolognesi**[7,8,9]

ABSTRACT—Many murine tumor models associated with murine leukemia virus(es) (MuLV) have been successfully treated by passive administration of antiviral antibodies. There is a large body of virus-negative tumors, however, which are lowly antigenic and thus refractory to such approaches. Therefore, an investigation was done for determination of whether such tumors could be rendered susceptible to passive serum therapy by introduction of MuLV antigens onto the tumor cell surface. For this purpose a 3-methylcholanthrene-induced fibrosarcoma from inbred C57BL/6J mice was chosen. Following infection of the tumor in vitro with Friend murine leukemia virus (F-MuLV), the tumor was found to be susceptible to treatment with a high-titered heterologous anti-F-MuLV gp71 antiserum. The specificity of the treatment was determined by conduction of the therapy on the uninfected parental tumor, in which case there was no effect. In addition, therapy could be initiated at time points when demonstrable tumors were present and successfully treated animals were resistant to rechallenge with the infected tumor. Thus conversion of a lowly antigenic virus-negative tumor to an MuLV-positive antigenic tumor rendered such growths susceptible to immunologic management.—JNCI 1982; 69:509–515.

Many murine tumor models are directly induced by or intimately associated with type C retroviruses. Such tumor cells usually express virus structural components on the cell surface, predominantly the virus envelope antigens gp71 and p15(E) (*1*). This has led to the development of immunotherapeutic regimens against MuLV-induced or -associated neoplasia, which utilize these antigens as specific targets for immunotherapeutic protocols. In this regard, both xenogeneic and syngeneic antisera against viral antigens have been shown to influence tumor growth in vivo in both the murine and feline type C retrovirus tumor systems (*2–5*). In contrast to tumors expressing retroviral antigens, virus-negative tumors, including many spontaneous or chemically induced neoplasms, are in general weakly antigenic, often producing an immune response difficult to measure (*6*). Although transplantation resistance may be elicited by immunization against such neoplasms (*7–12*), the antigens responsible for this phenomenon have proved difficult to isolate and identify (*13–16*). Moreover, each tumor, even when induced by the same chemical, has been shown to display unique transplantation antigens (*8, 9, 11, 17, 18*). Therefore, even if a therapeutic modality could be developed for such cancers by the use of these antigens, its applicability would be restricted to a single tumor.

An approach toward the successful immunologic management of such tumors could be derived from manipulations that would increase their antigenicity. To test this, we have chosen a chemically induced tumor arising in an inbred mouse strain and infected the tumor cells in vitro with a nonpathogenic MuLV. Subsequently, immunologic control of tumor growth was attempted by passive administration of antibodies directed against the major surface glycoprotein of the infecting virus. Our results, based on suppression of tumor growth, demonstrate that the superimposed viral antigen functions as an effective immunologic target in vivo.

MATERIALS AND METHODS

Mice.—All experiments were done with inbred C57BL/6J (B6) female mice used at 10–14 weeks of age (The Jackson Laboratory, Bar Harbor, Maine).

Virus.—F-MuLV was from a cell line derived from STU mouse embryo fibroblasts (Eveline) infected with F-MuLV (*19*). This cell line produces only the helper component of the Friend virus complex.

Cell lines.—A fibrosarcoma of B6 origin was induced in vivo with MCA and maintained in vitro. This line is designated MCA-FS and was provided by Dr. D. Adams (Department of Pathology, Duke University Medical Center, Durham, N.C.). An additional cell line was derived from this MCA-induced parental cell line in our laboratory by infection with F-MuLV and was designated MCA-FS-F-MuLV. Sarcoma-positive, leukemia-negative cells (Fg10) were obtained from Dr. P. J. Fischinger (National Cancer Institute, National Institutes of Health, Bethesda, Md.) and were used for determination of the ecotropic virus content of the cell lines. All 3 cell lines were grown as monolayers in

plastic T-flasks. Cell lines MCA-FS and MCA-FS-F-MuLV were grown in modified Eagle's minimum essential medium with 10% newborn calf serum, whereas the Fg10 cells were maintained in modified McCoy's 5-A medium containing 10% fetal calf serum (Grand Island Biological Co., Grand Island, N.Y.).

Infectious virus assay.—Ecotropic MuLV were titrated on Fg10 cells as previously described (*20*). Tissue culture supernatants were filtered (0.45 μm) prior to testing.

Sera.—Hyperimmune goat serum against purified F-MuLV gp71 was provided by Dr. Werner Schäfer (Max-Planck Institut Virusforschung, Tübingen, Federal Republic of Germany), and the corresponding IgG was prepared as described in (*2*). The IgG preparation appeared homogeneous on gels and was reconstituted to 15 mg protein/ml. The radioimmunoassay titer was determined as previously described (*21*) and was comparable to that of whole goat anti-gp71 sera. NGS was obtained from Dr. H.-J. Thiel (Bundesforschungsanstalt für Viruskrankheiten der Tiere, Tübingen, Federal Republic of Germany), and the IgG was extracted from it in a manner similar to that reported in (*2*). Rabbit antisera against R-MuLV gp71 and MuLV p30 were prepared as previously described (*19*). Rabbit anti-F-MuLV gp71 antiserum was provided by Dr. D. Bigner, Duke University Medical Center. Fluorescein-conjugated goat anti-rabbit IgG serum was obtained from Meloy Laboratories Inc., Springfield, Va.

IF.—IF with the rabbit anti-F-MuLV gp71 antiserum was performed as in (*22*). Monolayer cells were lightly trypsinized and washed three times with PBS; 1×10^6 cells were placed into dilution tubes. Each tube was incubated with 100 μl of either normal rabbit serum or rabbit anti-F-MuLV gp71 serum for 1 hour at 37°C. The cells were then washed three times with PBS and incubated with 100 μl of a mixture of fluorescein-conjugated goat anti-rabbit IgG (1:10 final dilution) and rhodamine counterstain (1:40 final dilution). After incubation for an additional 30 minutes at 37°C on a shaker platform, the cells were washed three times in PBS and dispersed in a drop of buffered glycerol. They were then mounted on glass slides, stored at 4°C, and examined within 24 hours for staining under UV illumination (Carl Zeiss, Oberkochen, Federal Republic of Germany). The results were expressed as an FI, where FI = (percent negative control cells − percent negative test cells)/percent negative control cells. An FI of greater than or equal to 0.20 is taken to reflect significant staining.

cRIA.—The methodology used in cRIA with the rabbit anti-R-MuLV gp71 and p30 has been described (*23*). We prepared cell extracts by washing cell monolayers with PBS and treating with disruption buffer [20 m*M* Tris-HCl and 100 m*M* NaCl (pH 7.6) with 1 m*M* EDTA and 1% Triton X-100]. The extracts were then sonicated and clarified by centrifugation first at 1,500 rpm (10 min) and then at 10,000 rpm (5 min). Protein content was determined by the method of Lowry et al. (*24*).

Inoculation of tumor cells.—Tumor cells for in vivo transplantation were prepared by light trypsinization with 0.05% trypsin and 0.1% EDTA in calcium-magnesium-free PBS, washed with PBS, and then enumerated. Cells were then inoculated sc in the dorsal region of the animal.

TABLE 1.—*Characteristics of tumor cell lines*

Cell line	Plaque-forming units/ml[a]	F-MuLV proteins, ng/mg protein[b]		LD_{50}[c]
		p30	gp71

[c] Determined by the method of Reed and Muench (*25*).

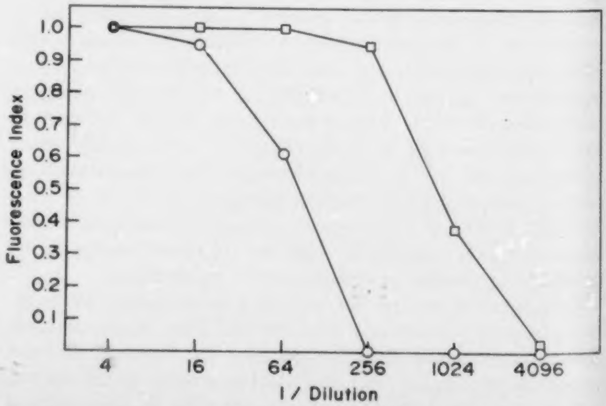
RESULTS

Characteristics of Tumor Cell Lines

To determine the amount of virus being produced by the cells, we tested culture fluids for the presence of viable virus in the Fg10 assay. Table 1 shows that the MCA-FS-F-MuLV cell line synthesized infectious virus, whereas the parental MCA-FS cell line was virus-negative.

The cell lines were also examined for viral antigen content in a cRIA. As can be seen in table 1, the infected cell line exhibited elevated levels of the internal virus structural protein p30 as compared to the uninfected parental line. Additionally, the assay for F-MuLV gp71 detected the envelope glycoprotein only in the MCA-FS-F-MuLV cells (table 1).

Because we intended to do passive immunotherapy studies using antiviral antibodies, we wanted to ensure that the appropriate virion antigen was prominently expressed at the cell surface. We therefore performed membrane IF analyses with the rabbit anti-F-MuLV gp71 antibodies. Text-figure 1 shows that the MCA-FS-F-MuLV cell line exhibits a significantly higher FI with the rabbit anti-F-MuLV gp71 serum than that of the parental cell line. The positive fluorescence with the MCA-FS cell line presumably reflects reactivity of group-specific antibodies in this serum with endogenous gp71 known to be expressed on some MCA-induced tumors (*26*).



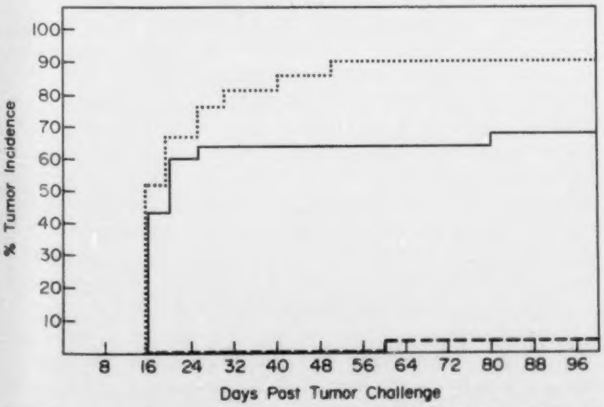
TEXT-FIGURE 1.—Immunofluorescent analysis of the MCA-induced cell lines with the rabbit anti-F-MuLV gp71 serum as described in "Materials and Methods." Parental non-virus-expressing MCA-FS cell line (○—○) was compared to MCA-FS-F-MuLV cell line (□—□).

Tumorigenicity

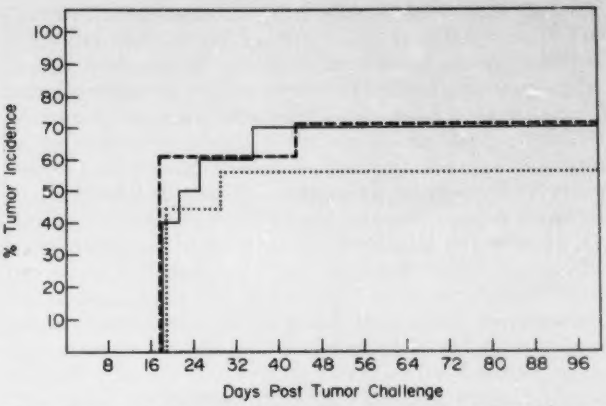
To determine the cell dose to use for tumor induction, we determined the tumorigenicity of each cell line by sc inoculation of graded numbers of tumor cells on the dorsum of the mouse. The infection of the parental cell line with F-MuLV, as compared to the uninfected parental cell line, was found to cause approximately a threefold increase in the number of cells needed to kill 50% of the animals (table 1). Thus, as predicted, infection with F-MuLV enhances antigenicity, although not to an extent that completely suppresses tumor growth. We therefore investigated the possibility that complete suppression of tumor growth could be achieved by administration of antiviral antibody. A challenge dose of three times the LD_{50} was used in all subsequent studies. This correlated to approximately 3×10^6 cells of MCA-FS-F-MuLV and 1×10^6 cells of MCA-FS per mouse.

Passive Serum Therapy of MCA-Induced Tumors

On the basis of our success using the hyperimmune goat anti-gp71 antisera in other tumor systems (*2-4*), we tested its therapeutic potential on mice inoculated with the MCA-FS-F-MuLV tumor cells. The basic serum therapy protocol consisted of ip inoculation of 0.5 ml whole serum or its equivalent, mixed with an equal volume of PBS, every other day. The therapy was initiated the day following tumor inoculation and continued for a course of six treatments, except where noted. Text-figure 2 is a composite of the results from four experiments on more than 25 mice per group. The goat anti-gp71 serum afforded a highly significant degree of protection (4% with tumors) when compared to the untreated controls (60% with tumors) and those mice treated with NGS (80% with tumors). To ascertain that the effect seen with the hyperimmune serum was specific for the infected cells, we subjected mice inoculated with the MCA-FS parental cell line to the identical treatment protocol. Text-figure 3 demonstrates that treatment with the goat anti-gp71 serum had no effect on either the latency or lethality of the MCA-FS.



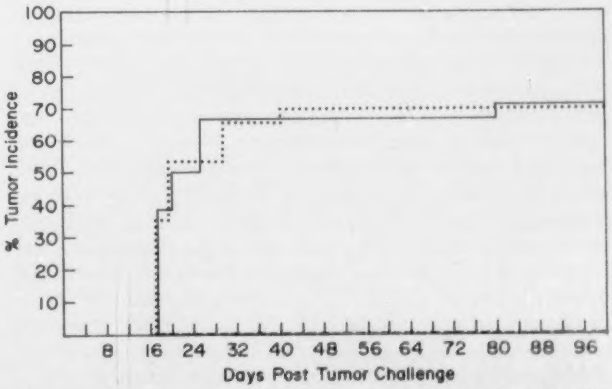
TEXT-FIGURE 2.—Treatment with goat anti-gp71 serum of mice challenged with MCA-FS-F-MuLV. No treatment (——), NGS treatment (···), or goat anti-gp71 treatment (- - -) were performed as described in "Materials and Methods."



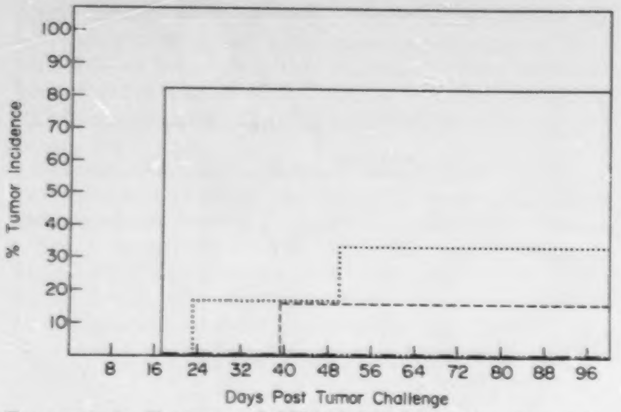
TEXT-FIGURE 3.—Treatment of MCA-FS tumor-bearing mice with goat anti-gp71 serum. Tumors were treated as in fig. 2. No treatment (——), NGS treatment (···), goat anti-gp71 treatment (- - -).

To investigate whether the protective effect of the immune serum truly reflected an antibody activity, we tested IgG preparations from both normal and hyperimmune goat anti-gp71 sera for their protective capability. Text-figure 4 is a composite of three experiments in which all of the animals treated with IgG equivalent to 0.5 ml of goat anti-gp71 serum per inoculum showed results of complete protection against outgrowth of tumor compared to a 70% tumor incidence in mice treated with normal goat IgG. These mice have been observed for longer than 1 year, and none of the protected animals have demonstrated any sign of tumor recurrence. Therefore, the protective activity resides in the IgG fraction of the hyperimmune serum.

In an effort to determine the effectiveness of the treatment in relation to tumor mass, therapy with purified IgG was initiated at varying time points after tumor inoculation. The results shown in text-figure 5 demonstrate that therapy may be initiated as late as 3 days post inoculation without the efficacy of the treatment regimen being decreased. Furthermore, serum treatment has an appreciable effect on the



TEXT-FIGURE 4.—Treatment of MCA-FS-F-MuLV with purified IgG. Mice challenged with MCA-FS-F-MuLV were treated with 500 µl whole-serum equivalents of normal goat IgG (···) or goat anti-gp71 IgG (- - -) or left untreated (——). Treatment was as described in fig. 2 legend.



TEXT-FIGURE 5.—Treatment of MCA-FS-F-MuLV-bearing mice with 500-μl equivalents of goat anti-gp71 IgG starting on days 1 (— —), 3 (·· ··), 5 (– – –), or 7 (···) and nontreatment (——) following tumor challenge. Therapy was continued for six courses of treatment from the time it was initiated.

tumor outgrowth even when begun as late as 7 days post inoculation.

Histologic Examination of Treated and Untreated Tumors

We next wished to determine whether the positive effect observed was directed against a definable tumor mass. Thus we performed autopsies on animals at various times following administration of the standard dose of tumor cells to ascertain the earliest time at which a demonstrable tumor was present. Animals autopsied as early as 2 days post challenge were found to bear histologically identified cancerous nodules (fig. 1A) with a well-defined capsule surrounding the tumor. By day 5 there was some necrosis at the center of the tumor, although the cells at the periphery appeared viable (fig. 1B). Several tumor cells were multinucleated and highly vacuolar, and in general the tumor appeared anaplastic with a wide heterogeneity in the size of both the cells and the nuclei. Additionally, there was little or no inflammatory reaction within the tumor sheath. In contrast to the appearance of a day-5 tumor in an untreated mouse, examination of the tumor nodule in a mouse after having received two inoculations of goat anti-gp71 serum revealed a large degree of tumor necrosis (fig. 1C). A marked inflammatory exudate, with large monocytes and plasmacytes was also present. The difference between treated and untreated tumors was even more pronounced by day 10, at which time there were virtually no viable tumor cells remaining in the serum-treated mouse (fig. 1E), while the untreated tumor (fig. 1D) progressed to the point that it was invading the underlying muscle and adipose tissue. The therapy protocol resulted in complete elimination of the tumor and was not an induction of tumor stasis inasmuch as treated animals, when autopsied 100 days after treatment, were found to have no histologic evidence of tumor.

Rechallenge of Treated Mice

Previous studies with virus-induced and associated cancers indicated that one important effect of successful immunotherapy was the development of a host immune response against the viral antigens (*4*, *27*, *28*). The biologic significance of such a response could be demonstrated since rechallenge of the animals with virus resulted in resistance to infection (*28*, *29*). To determine whether the current serum therapy protocol conferred any long-term immunity to tumor rechallenge in successfully treated mice, we rechallenged such animals with the standard dose of MCA-FS-F-MuLV cells (3×10^6) 200 days following cessation of the initial treatment protocol. As can be seen in text-figure 6, successful treatment led to functional immunologic memory, inasmuch as all of the treated animals remained tumor-free, whereas untreated age-matched controls developed lethal tumors.

DISCUSSION

As an approach toward the immunotherapeutic management of non-virus-associated, weakly antigenic tumors, a transplantable MCA-induced sarcoma was infected with a type C retrovirus (F-MuLV), followed by treatment with antiviral antibodies. The resulting data support the contention that if strong antigens can be introduced onto such tumors, these antigens can function as specific targets for the immune elimination of the growth. The optimum therapy protocol currently entails repeated large doses of a high-titered xenogeneic anti-F-MuLV gp71 serum (or the corresponding purified IgG) initiated after tumor inoculation. The main conclusions of this study are: 1) the beneficial effect seen with the treatment protocol is specific for the infected tumor as the parental non-virus-infected tumor is not influenced by the treatment protocol; 2) successful treatment of the MCA-FS-F-MuLV tumor can be initiated at times when well-established tumor nodules are present; 3) a significant proportion of animals can be successfully treated up to 7 days post tumor challenge; 4) the therapeutic protocol results in an increased inflammatory reaction at the site of inoculation, resulting in necrosis and eventual elimination of the tumor; and 5) successfully treated mice are resistant to rechallenge with the infected tumor as late as 6 months after the initial treatment.

Two concerns regarding the general applicability of this protocol pertain to potential harmful effects to the host of the virus as well as the introduction of such large quantities of foreign antibody. The virus used in these studies contains only the helper component of the Friend erythroleukemia virus stock and has no detectable oncogenic potential in the mouse strain utilized in these studies (*30*) presumably reflecting attenuation by prolonged passage in tissue culture. Likewise, animals inoculated systemically with this agent demonstrated no other adverse side effects inducible by infection with the helper F-MuLV (*30*). In addition, animals into which relatively large doses of F-MuLV (10^7 F-MuLV) were introduced did not exhibit a significant pattern of generalized infection (*31*), a consideration of importance in relation to the subsequent therapy with antiviral antibodies that could have an adverse effect on normal tissues expressing viral antigens.

The possible immunosuppressive effect of large amounts of anti-gp71 antibodies against T- and B-cells that express endogenous gp71 demonstrated by Wecker et al. (*32*) has been addressed in a similar therapy system by Schwarz et al. (*33*). They found that the treatment of AKR leukemia with comparable amounts of goat anti-gp71 IgG did not result in suppression of a T-cell-dependent humoral response. Although an adverse reaction (i.e., serum sickness and/or anaphylaxis) to the large amounts of foreign protein being administered in the treatment protocol is a possibility, no evidence of such a phenomenon has been seen in the current model.

The mechanism by which the antiviral antibodies affords protection to the tumor-bearing host, as well as the involvement of the host in the rejection process, has yet to be elucidated. However, the histologic examination of tumors shortly after the initiation of serum therapy revealed an increased inflammatory reaction when compared to untreated controls, suggesting that the rejection process is possibly mediated by a host effector cell. Preliminary results have indicated that serum-protected mice mount a humoral response to gp71 that does not arise until approximately 2 months after the treatment protocol. This finding is similar to the results seen by Schäfer et al. (*2*) in the STU F-MuLV system. Experiments are currently under way to delineate if this or other host responses are involved in the serum protection process.

The ability of successfully treated mice to resist a second tumor challenge with MCA-FS-F-MuLV cells as late as 6 months after serum therapy indicates that treated mice mount an immune response. In addition, preliminary studies show that treated mice also resist tumor outgrowth of parental MCA-FS cells. Confirmation of these results would suggest that virus infection of the MCA-FS cells has enhanced the immunogenicity of a cellular antigen responsible for tumor rejection in a manner similar to that described by Al-Ghazzouli et al. (*34*). Whether this increased immunogenic potential of the MGA-induced tumor antigens is necessary for effective therapy remains to be determined.

The results of this current paper form the basis for development of model systems for immunotherapy of weakly antigenic tumors. However, for such models to have practical value, the targeting of the tumor would have to be accomplished in situ. As we have previously reported (*30*), systemic administration of F-MuLV into mice bearing MCA-induced tumors resulted in efficient infection of the tumor. Additionally, minimal infection of normal host tissues was found in such animals (*31*). If therapy were to be initiated following in vivo infection, a prime concern would be the time at which all of the tumor cells are successfully infected. However, studies under way indicate that the tumor burden at this time may be too large for the current therapy to be effective. We hope to overcome this problem by establishing better therapy modalities as well as by increasing the efficiency of the in vivo infection process. In this regard, we have recently found that therapy with antiviral antibodies in the presence of rabbit complement has a greater benefit in the treatment of a Harvey virus-induced sarcoma than has the treatment with serum alone (Weinhold K: Manuscript in preparation). Presumably, if the parameters of the in vivo infection and therapy can be established for the system involved in MCA-induced tumors, then such findings could be extended to other systems involving naturally occurring tumors.

Proliferation of Ductal Outgrowths by Carcinogen-Induced Rat Mammary Tumors in Gland-Free Mammary Fat Pads[1,2,3]

Evelyn M. Rivera[4] *and* **Srinivasan Vijayaraghavan**[4,5]

ABSTRACT—The purpose of this study was to evaluate the gland-free mammary fat pad as a preferential site for transplantation of 7,12-dimethylbenz[*a*]anthracene (DMBA)-induced rat mammary tumors, since previous studies indicated their frequent failure to grow when transplanted in ectopic sites. Accordingly, samples from 14 primary mammary tumors (9 randomly selected and 5 ovarian-independent) were transplanted into the inguinal pairs of gland-free mammary fat pads of syngeneic female Lewis rats (9–12 wk of age). Although the percentage of takes was high (88%), the growth and morphogenetic capabilities of the transplants were strikingly different. Whereas transplants of ovarian-independent tumors consistently developed palpable carcinomas, transplants of all but 1 of the tumors selected at random (most of which were presumably ovarian-dependent) gave rise mainly to apparently normal ductal and hyperplastic outgrowths. The growth behavior of the transplants could not be correlated with the presence or absence in the tumors of mononuclear cells of the immune system. Unless the mammary fat pad selected against the growth of tumor cells, it seemed that the main alternative to tumor formation by the transplants was the proliferation of nontumorous outgrowths. These results draw attention to differences in the phenotypic stability of primary mammary tumors induced by DMBA and open up for further study the question of whether these differences reflect their cellular heterogeneity or their potential to undergo differentiation.—JNCI 1982; 69:517–525.

Mammary tumors induced in rats by the administration of DMBA frequently fail to grow when transplanted into subcutaneous and intramuscular sites (*1–4*). Even after autotransplantation, 33% of the mammary tumor transplants remain dormant in subcutaneous sites (*4*). Although the tumors have been serially transplanted in ectopic sites, the drawback is that they lose within a few generations the morphologic and hormone-dependent properties that characterized the primary tumors from which they originated (*2, 3, 5–7*). In the course of evaluating the mammary fat pad as a preferred site for transplantation, we noted that transplants of randomly selected DMBA-induced mammary tumors only infrequently grew to palpability but proliferated instead a variety of nontumorous outgrowths. In contrast, transplants of ovarian-independent mammary tumors consistently grew to palpability without forming outgrowths. These unexpected findings, which provide a new perspective on the growth potential of mammary tumors, are the subject of this paper.

MATERIALS AND METHODS

Rats.—Two sublines of Lewis strain rats were used in this study. They have been maintained separately and inbred by brother–sister matings in our laboratory since 1976. The original breeding pairs were obtained from the National Institutes of Health, Bethesda, Md. (strain LEW/SsN) and from Simonsen's Laboratories, Gilroy, Calif. (strain LEW/Sim). Mammary tumors were not cross-transplanted between the two sublines.

Induction of mammary tumors.—DMBA (20 mg; Sigma Chemical Co., St. Louis, Mo.) in sesame oil was administered to virgin females, beginning at 45–50 days of age, by gastric intubation in two feedings (10 mg each) 1 week apart. About 50% of the treated animals developed mammary tumors by 7 weeks, and by 16 weeks after treatment all animals had at least 1 mammary tumor. The age of the rats from which tumors were taken for study ranged from 16 to 22 weeks.

Preparation of mammary fat pads for transplantation.—The major pair of inguinal mammary fat pads of female rats was used as the site of transplantation. In rats, these fat pads contain the fourth and fifth pairs of mammary anlagen, which were removed surgically by cautery from 20- to 22-day-old females by a modification of the method of DeOme et al. (*8*). In our modification, the fat pad lymph nodes were removed, and the anesthetic used was ether rather than pentabarbital sodium. After surgery, wound clips were applied to the skin incisions, and the animals were held until transplantation.

Transplantation of mammary tumors.—Nine randomly selected primary tumors (≈1.0–1.5 cm in diameter), each from a different rat, were excised under sterile conditions. Portions of each tumor, excluding the capsule, were cut with the aid of a stereomicroscope into the approximately 1-mm cubes (to exclude pieces consisting only of connective tissue) and placed on saline-saturated filter paper in a petri dish. Tumor samples were transplanted singly into the gland-free mammary fat pads of syngeneic virgin hosts 9–12 weeks of age. In experiments A, B, and C (table 1), in which 2 tumors were used per experiment, samples from 1 tumor were transplanted into the right fat pad of each host, and samples of the second tumor were transplanted into the contralateral fat pad. Corresponding samples of the tumors were fixed in Carnoy's solution and processed for histologic examination.

Ovarian-independent tumors were also studied when it was recognized that tumors selected at random generally

failed to grow to palpability. In these cases, rats bearing primary mammary tumors were bilaterally ovariectomized, and samples from 5 tumors that continued to grow after ovariectomy (≈1.0–1.5 cm in diameter) were transplanted into gland-free mammary fat pads as described above.

Evaluation of growth and morphogenetic capabilities of the tumors.—Within 1 week after transplantation, mammary fat pads were palpated for tumors twice weekly. Tumor latency was determined to be the number of days elapsing between transplantation and initial palpability of the tumor. Tumors were allowed to grow until they were at least 1.0–1.5 cm in diameter before termination. At this time, samples of tumors (if present) were removed for histologic examination, and the remaining fat pads were removed intact, spread on filter papers, and fixed on the papers in buffered 15% Formalin; the papers were removed after fixation, and the fat pads were processed for wholemount examination as described previously (*9*).

In cases in which no palpable growths occurred, the animals were usually held for 1 year before termination, and the mammary fat pads were processed as described above for whole-gland examination. Each fat pad was evaluated according to the growth patterns found, which are listed in tables 1 and 2. Representative portions of the outgrowths were removed and processed for histologic examination. Photographs were taken of some of the wholemounts and of the portions removed for histologic examination.

RESULTS

Transplantation of randomly selected mammary tumors.—The primary tumors that provided the transplants were mammary adenocarcinomas (figs. 1, 2) with histologic variations (*10*) within and among different tumors. In 4 of the 9 primary tumors, the intraepithelial stroma was infiltrated with mononuclear cells, mostly lymphocytes (fig. 2). Those tumors showing this infiltration were one of the two sources used in experiment A and the sources of experiments D, E, and F (table 1). However, there was no correlation between growth fates of the tumors and the presence of lymphocytes.

The overall results are summarized in tables 1 and 2. The major finding was that although nearly 90% (87/100) of the transplants did take in mammary fat pads, most transplants (70%, 61/87) gave rise to outgrowths that were predominantly ductal or ductal-alveolar in morphology (figs. 3–6, 10, 12, 18, 21). DH and/or alveolar hyperplasias were also present in many of the outgrowths (figs. 3, 6, 12, 13, 18, 19), but only a few outgrowths contained tumors (figs. 7, 8, 21, 22). Transplants developing palpable tumors generally did not proliferate outgrowths (24%, 21/87), and 17 of the 21 transplants of this type were from a single tumor source (*see* below). Of the transplants, 7% formed localized atypical ducts (figs. 14–16).

Variations among the primary tumor sources.—As noted above, all but 1 of the 9 randomly selected tumors produced outgrowth in mammary fat pads. The exception was the tumor source in experiment D (tables 1, 2), from which all samples gave rise to palpable carcinomas. In general, transplants that proliferated outgrowths rarely developed palpable tumors (table 1). Only two tumor sources gave rise to regressing tumors (experiment B, table 1).

Variations among transplants from individual tumors.—In experiment A (table 1), the same tumor was the source of both a palpable adenocarcinoma and a nonpalpable adenoacanthoma. In experiments E and F (table 1), transplants from both tumor sources generated outgrowths, palpable and nonpalpable tumors, and localized takes, but the tumor source in experiment F gave rise to a broader spectrum of outgrowths than did the source in experiment E (table 2).

Histologic examination of the mammary outgrowths.—The epithelial portions of the outgrowths that were ductal, ductal-alveolar, and hyperplastic-alveolar in subgross appearance were shown by histologic examination to consist of normal-appearing, cuboidal cells with scant cytoplasm (figs. 15, 23). There were variations in the same outgrowth in the size and shape of the cells (cf. figs. 15, 17, 20) and in the thickness of the connective tissue stroma (cf. figs. 15, 17). DH occurred at terminal portions of ducts (TDH) (fig. 9) and in proximal portions (figs. 18, 19). Hyperplasias also varied in size, number, and shape (cf. figs. 9, 19) and in the amount of associated connective tissue (cf. figs. 9, 13). Other atypias included atrophic ducts and structures with variable histol-

TABLE 1.—*Growth potential of mammary tumors transplanted into gland-free mammary fat pads*

[a] A portion of most of the outgrowths was ductal or ductal-alveolar in morphology, regardless of whether other growths (tumors or hyperplasias) were also present.

ogy (figs. 13, 19, 22) that appeared as microscopic densities in wholemounts (figs. 12, 18, 21).

Tumor latencies.—The latencies for palpability (excluding tumors that regressed after initial palpability) ranged from 9 to 119 days ($\bar{x}$, 32 days). If we consider separately the case in which all transplants from a single source gave rise to palpable tumors without outgrowths (experiment D, table 1), the latencies were 9–51 days ($\bar{x}$, 19 days). In contrast, the latencies of the remaining tumors ranged from 28 to 119 days ($\bar{x}$, 61 days). Latencies of the tumors that regressed after initial palpability were 25–78 days ($\bar{x}$, 41 days).

Transplantation of ovarian-independent tumors.—These tumors were remarkably consistent in developing palpable tumors without also forming outgrowths. Five ovarian-independent tumors were the sources of 32 transplants in the fat pads of 16 hosts, of which 88% took (28/32) and grew to palpability. Only 2 of the 28 transplants produced outgrowths as well as tumors, and these outgrowths were ductal–alveolar in morphology and derived from the same tumor. Latencies for palpability were 9–53 days ($\bar{x}$, 28 days). The tumors and their transplanted derivatives were adenocarcinomas (fig. 25). Only one of the five sources was infiltrated with lymphocytes, but all transplants from that source developed tumors without outgrowths.

DISCUSSION

It is now well documented that transplants of normal and hyperplastic mammary tissue proliferate better in gland-free mammary fat pads of syngeneic hosts than in ectopic sites (*8, 11, 12*). It was therefore expected that transplants of DMBA-induced mammary tumors, which frequently failed to grow in ectopic sites (*1–4*), would develop palpable carcinomas in mammary fat pads, their normal site of development. However, as the present study shows, this was not always the case.

Despite the high percentage of takes, there was a striking difference in the growth and morphogenetic capabilities of the tumors. Most of the transplants of *randomly selected* tumors proliferated mainly ductal and ductal–alveolar outgrowths, with and without hyperplastic components, but only rarely did they develop palpable tumors. In contrast, transplants of *ovarian-independent* tumors consistently gave rise to palpable tumors but rarely to outgrowths. This last finding and the fact that most mammary tumors induced in rats by DMBA are ovarian-dependent (*6, 13–16*) suggest that most of those selected at random were ovarian-dependent. This characteristic is consistent with the finding that transplants of only 1 of 9 randomly selected tumors gave rise to tumors without outgrowths (as did the ovarian-independent tumors), and transplants from only two sources displayed spontaneous regression (see table 2).

The major questions raised by this study concern the differential growth behavior of the tumors, i.e., why the ovarian-dependent majority formed nontumorous outgrowths, whereas the ovarian-independent minority were more likely to "breed true" and give rise only to palpable carcinomas.

We considered the possibility that the nontumorous outgrowths were a reflection of the heterogeneous cell composition of the tumors and therefore the result of proliferation of preexisting normal and hyperplastic cells. Although cellular heterogeneity may account in part for the diversity in outgrowth morphology as well as in the proliferative potential of randomly selected tumors, what was remarkable was the infrequency with which transplants of these tumors gave rise to palpable carcinomas. Thus if preexisting cell variants were the major source of the outgrowths, this would imply that selection occurred in the mammary fat pads against the growth of tumor cells. This possibility is difficult to reconcile with the fact that the tumors did originate and grow in the fat pads in the first place. Furthermore, assuming that the tumors were heterogeneous (i.e., each differing in content of normal, hyperplastic, and tumor cells), then some of the transplants from all of the tumor sources should have developed palpable tumors. However, this activity did not occur with most tumors selected at random.

Differences in the hormonal environment and microenvironment of the transplant recipients (9- to 12-wk-old virgins) and transplant donors (16- to 22-wk-old DMBA-treated virgins) may exert some selection in the transplants. Experiments are planned to pursue this possibility. One study in progress indicates that pretreatment of the recipients with DMBA does not enhance the formation of palpable growths from transplants of randomly selected tumors.

The possibility that immune rejection could account for the growth failure of the tumors was also considered, since these tumors have been found to express tumor antigens (*2, 17*). Although tumor immunogenicity was not studied, histologic studies revealed no correlation between the presence of mononuclear cells in the tumor sources and their subsequent behavior on transplantation. Portions of some outgrowths did contain lymphocytes (see fig. 16), but most did not. Perhaps the strongest argument against immune rejection playing a significant role in tumor growth failure was the invariability with which ovarian-independent tumors grew to palpability. Moreover, even with well-defined rejection antigens, tumors are still able to grow progressively (*18*).

Whatever the ultimate explanation, the remarkable finding was that tumor transplants that failed to breed true appeared to have other growth options: generally, to proliferate normal-appearing and hyperplastic outgrowths or, more infrequently, to proliferate mixed tumor–ductal outgrowths or to form localized ducts (limited proliferative potential). If our assumption that the mammary fat pad does not select against tumor cells is correct, then an alternative explanation for the development of outgrowths is that it reflects the potential of the tumors to undergo differentiation. Transplantation into gland-free mammary fat pads must in some way have triggered the expression of this potential. This indicates that the neoplastic phenotype is not a fixed property of most DMBA-induced mammary tumors but is subject to modulation. Conversely, the general failure of ovarian-independent tumors to form outgrowths implies a more stable phenotype in autonomous than in dependent tumors. As occurs in normal differentiation, the number of avenues open to a cell becomes decreased as it becomes committed to a particular phenotype. A similar commitment may hold for ovarian-independent tumor cells.

That most DMBA-induced mammary tumors are ovarian-dependent (*6, 13–16*) and at least some are spontaneous regressors (*15, 19*) may be viewed as evidence for their phenotypic lability and sensitivity to environmental shifts. Indeed, the phenotypes of other tumors can be altered and even normalized by shifts in their microenvironment (*20–24*), and it is possible that the gland-free mammary fat pad represents an environmental shift for mammary tumor cells. Pregnancy-dependent mammary tumors in mice also appear to be phenotypically labile, since during serial transplantation they alternate between ductal and tumorous phases of growth, depending on the hormonal environment (*25*). We plan also to determine whether similar alternation occurs in carcinogen-induced mammary tumors, and to this end we are attempting to develop a serially transplantable ductal tissue line derived from a tumor (fig. 26).

Although cloning studies of the tumors are clearly needed to specify the cellular origin of the mammary outgrowths, the absence of specific markers for mammary tumor cells (except for their tumorigenicity in vivo) poses problems. For example, anchorage independence in agarose cultures, a widely used criterion for tumorigenicity, is not always linked to mammary tumorigenicity in vivo (*26*). Furthermore, both anchorage-dependent and anchorage-independent cell lines from mouse mammary tumors have been shown to be tumorigenic in vivo (*27*), indicating that the tumor cells themselves are heterogeneous.

Nevertheless, the recent work of Dulbecco et al. (*28, 29*) and Rudland et al. (*30, 31*) is of special relevance to the present study. These researchers have developed cell clones derived from DMBA-induced rat mammary tumors, which give rise in vitro to normal-appearing mammary cells. One clonal line, Rama-25, may be a stem cell line since it gives rise to the main differentiated cell types of the mammary gland (*31*). Furthermore, depending on the composition of the medium (*29*) or of the substrate (*32*), the clones form structures that may be analogous to normal mammary ducts, ductal end buds, and hyperplasias. Thus our results may be in the in vivo counterpart for these studies in cell culture.

In a broader context, there is considerable evidence for tumor cell heterogeneity (*33–35*) and increasing evidence for the differentiative potential of tumor cells (*36–39*). Thus while it is possible that the growth characteristics reported here may be peculiar to certain types of mammary tumors, they open up for further exploration the question of their heterogeneous cell composition and/or potential to undergo differentiation.

Individually Distinct Tumor-Specific Cell Surface Antigen Identified by Monoclonal Antibody on a Rous Sarcoma Virus-Induced Mouse Tumor[1,2]

Noboru Kuzumaki,[3,4] **Hidetaka Minakawa,**[3] **Takashige Miyazaki,**[3] **Soichi Haraguchi,**[3] **Tetsumichi Matsuo,**[3] *and* **Takato O. Yoshida**[3,5]

ABSTRACT—Hybrid cell lines were prepared by the fusion of BALB/c myeloma P3U-1 cells with the lymphocytes of BALB/c mice that were immunized with syngeneic Rous sarcoma virus (RSV)-induced tumor CSA1M cells. Three clones of the hybrid progeny (3.4B2, 3.4C6, and 3.5C11) produced cytotoxic IgM antibodies against CSA1M cells. One of the clones, 3.5C11, was chosen for analysis of the detailed specificity. Both direct cytotoxicity assays and absorption tests revealed that monoclonal antibody from 3.5C11 was positive only with CSA1M cells and that it failed to react with other tumors, including 20 RSV-induced mouse tumors, and normal cells. The 3.5C11 monoclonal antibody alone, with or without exogenous complement, was suppressive in the therapy of ip injected CSA1M tumor in syngeneic hosts, and significant prolongation in survival was seen in the treated mice. These results clearly showed presence of an individually distinct tumor-specific cell surface antigen on an RSV-induced mouse tumor.—JNCI 1982; 69:527–530.

Chemical carcinogen-induced tumors carry surface antigens that are generally unique to each tumor and do not cross-react with other tumors in vivo, even when these are induced by the same carcinogen in the same strain of mice and have the same morphology (*1*). Conversely, all tumors induced by an oncogenic virus, even those induced by that virus in different species of rodents, share cross-reacting tumor-associated antigens. In addition to common antigens, however, individual specificities of non-virus-associated antigens have been demonstrated in murine mammary tumor virus-induced tumors (*2, 3*), SJL mouse reticulum cell sarcomas (*4*), SV40-induced tumors (*5*), AKR mouse leukemias (*6*), and feline leukemias (*7*).

In the ASV system, ASV-induced avian and mammalian tumors express a common TSSA (*8*). Recent progress in the production of monoclonal antibody in vitro (*9*) has prompted many investigators to use this technique to investigate cell surface antigens on tumor cells in experimental animal (*10–13*) and human (*14–17*) systems.

We have used this approach and obtained a syngeneic monoclonal mouse antibody that identifies a new individually distinct TSSA of an RSV-induced tumor.

MATERIALS AND METHODS

Mice.—Mice BALB/cCrl mice were obtained from Shizuoka Argicultural Cooperative Association for Laboratory Animals, Hamamatsu, Japan. Homozygosity of the inbred mice was identified by genetic monitoring with use of biochemical markers of Id-1, Dip-1, Car-2, Mup-1, Gpd-1, Pgm-1, Ldr-1, Gpi-1, Hbb, Es-1, Es-2, Es-11, Prt-2, Mod-1, Trf, Es-3, and Ce-2.

Cells.—The cell lines used in this work are the following: The SR-RSV-induced mouse tumors CSA1M, CSA7M, CSA8M, CSA9F, CSA10F, CBr2F, C3SA1F, B6SA3F, BDSA3F, B10Br2F, D2SA1M, B10ABr2M, and B10ABr1F. C, C3, BD, and D2 stand for mouse strains BALB/c, C3H, BDF_1, and B10D2. SA and Br stand for sarcoma and brain tumor, 1–10 for the serial number of the tumor, and M and F for male or female. These tumors were established in our laboratory (*18*). S1018.B10, S908.D2, S623.BR, S826.BA, S1229.4R, S325.5R, S319.BS, and S208.9R are also SR-RSV-induced tumors and were provided by Dr. S. Fujimoto (Kochi University School of Medicine, Kochi, Japan). Three MCA-induced tumors (MCSA4M, MCSA2F, and CMC-11; obtained from Dr. T. Takahashi, Aichi Cancer Center, Nagoya, Japan), 3 murine leukemias (RL♂1, Kaplan-1, and P815; also from Dr. T. Takahashi), and a wild mouse embryo cell line (SC-1; obtained from Dr. A. Ishimoto, Virus Research Institute, Kyoto University, Kyoto, Japan) were also used. A Fischer rat fibroblast line 3Y1 and SR-RSV-transformed 3Y1 line were provided by Dr. S. Kawai (Research Institute of Medical Science, Tokyo University, Tokyo, Japan), and B77ASV-transformed 3Y1 was a gift from Dr. H. Mitsui (Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan). Eight human cell lines were also used: Namalva, Raji, and RPMI 8226 (from Dr. G. Klein, Karolinska Institute, Stockholm, Sweden), CCRF-CEM (from Dr. M. Katagiri, Asahikawa University School of Medicine, Asahikawa, Japan), K562 (from Dr. Y. Koide, Hamamatsu University School of Medicine, Hamamatsu, Japan), SK-MEL-28 (from Dr. T. Takahashi), SCH (established by Dr. S. Ooboshi, Niigata University School of Medicine, Niigata, Japan), and A204 (from Dr. M. Hatano, Cancer Research Institute, Kanazawa University, Kanazawa, Japan). All cell lines were maintained in DMEM or RPMI-1640 medium supplemented by 5–10% newborn or

FCS and antibiotics. 8-Azaguanine-resistant BALB/c myeloma cells, P3U-1, were provided by Dr. T. Watanabe (Saga University School of Medicine, Saga, Japan). This line originated from Dr. M. D. Scharff (*19*). P3U-1 cells were grown in RPMI-1640 medium supplemented with 10% FCS and L-glutamine (300 mg/liter). Embryo cells from 14-day gestation BALB/c and NZB/Ta1 embryos (from Dr. T. Shirai, Kyoto University School of Medicine, Kyoto, Japan) and normal spleen cells from BALB/c, C57BL/6, C57BL/10, B10.D2, BALB.B, CBA, B10.BR, B10.A, B10.A(3R), B10.A(5R), BTK/Osb (from Dr. Kawamata, Microbiological Disease Institute, Osaka University, Osaka, Japan), NZB/Ta1, and NZW/Ta1 (from Dr. T. Shirai) were also used.

Production of hybridomas.—Male BALB/c mice, 6 weeks old, were immunized by 2–4 weekly ip inoculations of both 5–100×10^3 viable and 1×10^7 mitomycin C-treated CSA1M cells and were killed 4 days after the last injection. The fusion of immune splenocytes with mouse myeloma P3U-1 cells was performed by the addition of a mixture of 30% polyethylene glycol 1500 (Katayama Chemical Co. Ltd., Nagoya, Japan) and 10% dimethyl sulfoxide in RPMI-1640 medium. Fused cells were seeded in wells of tissue culture plates (Falcon #3040). Hybrids were selected according to establish techniques in a medium containing hypoxanthine–aminopterine–thymidine (*20*). Supernatants were screened for cytotoxicity against cultured CSA1M cells and other target cells with the use of microcytotoxicity assays. Established hybridoma cultures were cloned by limiting dilutions. Hybridomas were expanded by growth in tissue culture and were also grown in the peritoneal cavity of BALB/c mice.

Immunoglobulin isotypes were determined by the Ouchterlony technique with the use of goat anti-mouse IgG_1, IgG_2, and IgM (obtained from Meloy Laboratories, Inc., Springfield, Va.) and rabbit anti-mouse IgG_3 (Miles Laboratory, Inc., Elkhart, Ind.).

CDC assays.—A microassay was used; 2 µl of serial dilutions of culture supernatants or of ascitic fluid were injected under paraffin oil into wells of a Terasaki Microtest plate (Falcon #3034). To each well 1,000 target cells in 1 µl were added, and the plates were incubated for 20 minutes at 37°C. Subsequently, 1 µl rabbit complement was added. Plates were further incubated for 45 minutes. Thereafter, 0.5 µl trypan blue was added to each well, and the results were read microscopically. CI was calculated as follows: $CI=1-t/c$, where t=the percentage of unstained cells in the test sample and c=the percentage of unstained cells in the control sample. A CI exceeding 0.20 was regarded as positive.

Absorption test.—An equal volume of culture supernatant containing hybridoma antibodies, diluted one or two wells below the CI of 0.50 to the CSA1M cells, as well as the washed packed cells (5×10^6) to be tested were incubated for 30 minutes at 37°C and then for 30 minutes at 4°C. Thereafter, the mixtures were centrifuged. After centrifugation, the residual cytotoxicity of the supernatants was measured at 1:1 and 1:2 dilutions against the CSA1M cells by CDC assays. Percent absorption (Ab) was calculated as follows: Percent $Ab=(1-a/u)\times100$, where a=CI by absorbed culture supernatant and u=CI by unabsorbed culture supernatant. A percent Ab less than 20% was regarded as negative.

Immunotherapy.—Fifty-seven male BALB/c mice (6 wk old) were each inoculated ip with 5×10^5 syngeneic CSA1M cells (a dose 1 log >100% lethal dose). The mice were then separated into 5 groups for treatment, which was initiated 2 hours after tumor inoculation and continued for 4 days. All injections were made ip. Mice in 1 test group were each given an injection of 900 µl ascitic fluid containing monoclonal antibody (20 mg) to CSA1M cells with a titer of 7×10^{-5} in CDC assays. Mice in 2d group were each given an injection of 100 µl suckling rabbit serum, which did not show any cytotoxicity for CSA1M cells in vitro. Mice in a 3d group each received an injection of 900 µl ascitic fluid containing antibody and 100 µl suckling rabbit serum. Two additional groups were used as controls; one 900 µl P3U-1 ascitic fluid, whereas the other was untreated. They were kept for an observation period of 90 days.

RESULTS

Two out of 17 fusions produced hybridomas, some of whose supernatants showed activity against CSA1M cells. In the first experiment, 2 hybridomas were reactive not only with CSA1M cells but also with other RSV-induced mouse tumors, CSA9F or B6SA3F, but neither reacted with the MCA-induced mouse tumor MCSA4M or the BALB/c leukemia RL♂1. After repeated testing, these hybridomas showed gradually decreasing reactivity with the CSA1M cells. The other hybridomas 3.4B, 3.4C, and 3.5C reacted exclusively with CSA1M cells and remained strongly and consistently positive against CSA1M cells. These hybridomas were cloned by the limiting dilution method, and clones that were found to produce a high titer of antibody reactive with the CSA1M cells were isolated. A supernatant of 3.5C11 and ascitic fluid or serum from 3.5C11-bearing BALB/c mice showed very strong cytotoxicity against CSA1M cells with titers of 1:5,120, 1:409,600, and 1:409,600, respectively (table 1). Two other clones, 3.4B2 and 3.4C6, had similar titers. Determination of immunoglobulin class showed that all the antibodies secreted by 3.4B2, 3.4C6, and 3.5C11 were IgM.

One of the clones selected, 3.5C11, has been extensively tested for specificity against various target cells (table 2). Using culture supernatant from 3.5C11, we saw no cytotoxicity with 20 other RSV-induced tumors from 12 different

TABLE 1.—*Titer and immunoglobulin class of cytotoxic antibodies produced by cloned hybridomas in culture supernatant, ascitic fluid, and serum against CSA1M cells*

Hybridomas	Cytotoxicity titer[a] with:			Immunoglobulin class
	Culture supernatant	Ascitic fluid	Serum[b]	
3.4B2	2,560	204,800	NT	IgM

mouse strains, a rat fibroblast cell line transformed by SR-RSV or B77ASV, MCA-induced mouse tumors, 3 murine leukemias, P3U-1 cells, or 8 human tumor cell lines. The hybridoma antibody was also tested against normal cells; a wild mouse embryo fibroblast line, SC-1, BALB/c, and NZB embryo cells at 14-day gestation, normal mouse splenocytes from BALB/c, NZB, B10.D2, C57BL/6, C57BL/10, BALB.B, BTK, CBA, B10.BR, NZW, B10.A, B10.A(3R), and B10.A(5R), and a noninfected rat fibroblast line, 3Y1. All tests were negative at all serial dilutions of the hybridoma culture supernatant from 1:10 out. Even ascitic fluid from 3.5C11-bearing mice was noncytotoxic to target cells other than those of CSA1M (data not shown). Absorption tests showed that the antibody secreted by hybridoma 3.5C11 completely lost its cytotoxicity for CSA1M cells when preabsorbed with CSA1M cells. Other tumors and normal cells did not absorb the cytotoxicity of the hybridoma antibody for CSA1M cells (table 2).

For its therapeutic activity in vivo against a transplant of CSA1M cells, as shown in table 3, CSA1M cells inoculated into peritoneal cavity grew progressively in the treated and untreated mice. The median survival time for mice treated with rabbit serum or P3U-1 ascitic fluid alone and untreated mice was from 21 to 23 days. In contrast, mice treated with the 3.5C11 ascitic fluid alone or with the ascitic fluid and rabbit serum as exogenous complement showed prolonged survival, with a median of 33 and 37 days, respectively.

DISCUSSION

It was previously demonstrated that SR-RSV-induced mouse tumors had common TSSA and transplantation antigens (*8*). Using transplantation resistance, Bubeník et al. (*21*) suggested that in addition to a group-specific antigen shared by tumors induced with different variants of RSV, SR-RSV, Prague-RSV, and Bryan-RSV, there were specific antigens for individual tumors. We know of no report concerning the presence of individually distinct antigens on different tumors induced by the same type of RSV.

We have demonstrated an individually distinct antigen at the cell surface of an SR-RSV-induced mouse tumor by serologic technique using monoclonal antibodies from hybridomas. The antigen is not shared by any of a wide range of tissues tested, including other mouse or rat tumors induced by SR-RSV or B77ASV, chemically or physically induced mouse tumors, murine leukemias, various human tumor cell lines, mouse and rat embryo cells, and normal spleen cells from various strains of mice.

This strongly suggests the previously canvassed possibility (*3*) that individually distinct antigens on virus-induced tumors are overshadowed in conventional transplantation tests and serologic studies with the use of immune serum by cross-reactive antigens. The presence of the individually distinct antigen on an SR-RSV-induced mouse tumor indicates that it was at least partly coded by a cellular gene, as in tumors induced by chemical carcinogens. The integration or interaction of the viral genome with the cellular genome, if it occurs, would most often occur in a defined and confined site providing the basis for common antigens. A slight shift of the integration or interaction site may occasionally occur, leading to the expression of individual antigens that coexist with the common antigen.

It has been shown by serologic, histogenetic, and biochemical approaches that murine tumors of different etiologic origins may express alien H-2 and non-H-2 histocompatibility antigens (*22, 23*). That the individually distinct antigen on our RSV mouse tumor is such an alien histocompatibility antigen is unlikely since several anti-H-2 sera showed no alien H-2 antigens at the cell surface of CSA1M cells that expressed the individually distinct antigen (Mizuno M: Unpublished observation), and the unique antigen was not expressed on other normal and tumor cells from a range of mouse strains including congenic and recombinant mice.

All vertebrate normal cells possess one or a few genes (*c-src*) homologous with the ASV *src* gene (*24*). Such sequences are expressed, at a low frequency, as a 60,000-dalton phosphoprotein, pp60$^{c\text{-}src}$ (*25–28*). Hanafusa et al. (*29*) and Vigne et al. (*30*) have shown that viruses with partial deletion of the *src* gene can recover a fully functional *src* gene during passage through a chicken. Partial analysis of the sequence of the *src* gene of the recovered viruses suggests that much of it is derived from the cellular *src* gene (*31*). Parsons et al. (*32*) showed that injection of RSV-transformed cells into syngeneic mice resulted in an antiserum specific for the ASV gene product pp60^{src}. Analysis of the cross-reactivity of these antisera demonstrated at least three to four antigenic determinants on $pp60^{src}$ including one cross-reactive with normal cell *src* protein. Whether the monoclonal antibody from our hybridoma recognizes an antigen associated with the cellular *src* gene remains to be analyzed.

One of the important questions to be answered is whether the serologically defined antigens correspond to transplantation antigens. In this report, using monoclonal antibody, we have demonstrated that antibody against an individually distinct TSSA is responsible for the tumor growth inhibition. These results suggest that the unique TSSA on an RSV-induced mouse tumor can function as a transplantation antigen.

Neoplastic Transformation of Syrian Hamster Cells by Putative Epoxide Metabolites of Commercially Utilized Chloroalkenes[1,2]

Joseph A. DiPaolo[3,4] *and* **Jay Doniger**[3,5]

ABSTRACT—The transforming ability of six epoxides of structurally related chloroalkenes was determined with a quantitative Syrian hamster embryo cell model. The epoxides used were *cis*-1-chloropropene oxide (*c*-CPO), *trans*-1-chloropropene oxide (*t*-CPO), *cis*-1,3-dichloropropene oxide, *trans*-1,3-dichloropropene oxide, trichloroethylene oxide (TCEO), and tetrachloroethylene oxide (PCEO). All six epoxides induced morphologic transformation of Syrian hamster embryo cells and caused cell lethality as reflected in the reduced cloning efficiency; in all instances, transformation was observed with less than 25% toxicity. The potency of the various epoxides was influenced by the difference in stability of the compounds. The results with *c*-CPO, *t*-CPO, TCEO, and PCEO were consistent with a linear dose response. The transformation results reflect the carcinogenicity of the parental chloroalkenes tested thus far. Furthermore, if the epoxides are metabolic intermediates of the chloropropene parent chloropropenes, the epoxides are probably proximate carcinogens.—JNCI 1982; 69:531–534.

The observation of angiosarcomas and portal cirrhosis of the liver in workers exposed to vinyl chloride monomer was followed by a series of experiments in animals to reproduce the disease (*1*, *2*). More recent investigations have demonstrated that the mutagenic effect of vinyl chloride occurred after metabolic activation in yeast and bacteria (*3–6*). In addition, malignant transformation of embryonic Syrian hamster cells occurred only after pregnant hamsters were exposed to the compound at fairly high concentrations of 20% (vol/vol) in air and not by direct treatment of the cells (*7*). Therefore, the preponderance of the results indicates that vinyl chloride gives rise to metabolites responsible for mediating the various deleterious effects. The highly reactive chloroethylene oxide is considered the most plausible of these metabolites and, as discussed by Van Duuren (*8*), is probably responsible for the carcinogenic action of vinyl chloride. Evidence for this assumption is based on experiments in which 3,4-dichlorobenzenethiol served as a trapping agent for the reactive metabolites formed in vitro from vinyl chloride in the presence of a liver microsomal system (*9*). Epoxide derivatives from chlorinated olefins including the one from vinyl chloride are direct-acting mutagens in both bacteria and yeast (*6*, *10*, *11*). The mutagenicity was correlated with the reactivity of the postulated epoxide intermediates of six chlorinated olefins of economic importance (*10*).

In the present work, the transformation of Syrian hamster cells by this series of six epoxides from chloro-olefins was determined and the transforming ability of these epoxides was compared to their mutagenicity so that we could obtain a measure of their relative activities. The results of this study provide insight into the potential carcinogenicity of the parental chloroalkenes. The epoxides *c*-CPO, *t*-CPO, *c*-DCPO, *t*-DCPO, TCEO, and PCEO (text-fig. 1) were synthesized and characterized by Kline et al. (*12*). The comparative study on the transformation as a function of exposure dose suggests that *c*-DCPO and *t*-DCPO are the most effective compounds.

MATERIALS AND METHODS

Chemicals.—The *c*-CPO, *t*-CPO, *c*-DCPO, and *t*-DCPO were obtained by *m*-chloroperbenzoic acid oxidation of the two parental chloroalkenes; PCEO was the reaction solvent. The *c*-DCPO and *t*-DCPO were similarly prepared from the corresponding alkenes except that the reactions utilized methylene chloride as solvent. The TCEO and PCEO were synthesized by auto-oxygenation of the TCEO and PCEO, and the chloride by-products formed were removed by extraction with 0.5 *N* sodium hydroxide. All compounds were provided pure as determined by nuclear magnetic resonance analysis (*12*) and were stored at −70°C.

Cell cultures.—Hamster cells were derived from Syrian hamster embryos at 12–13 days of gestation as described (*13*). We obtained primary cultures from trypsinized embryos by seeding 10^7 cells/100-mm dish. We prepared secondary cultures 2–3 days later by seeding 5×10^6 cells/10 ml in complete medium in 100-mm dishes. Mass cultures were grown in modified Dulbecco's minimum essential medium supplemented with 10% fetal bovine serum (*14*) in incubators in an 11% CO_2 atmosphere.

Hamster embryo cell transformation assay.—Three hundred cells from the secondary cultures were plated in complete medium with 20% serum in 60-mm plastic dishes along with 6×10^4 cells that had been irradiated as confluent monolayer cultures. The feeder cells were irradiated with a total of 4,400 rad in air at a distance of 22 cm. After 2-day incuba-

TEXT-FIGURE 1.—Structures and stability of chloroalkene oxides. Half-life values are in minutes and were measured at pH 7.4 and 37°C as determined by Kline et al. (*12*).

Compound	Structure	Half-Life(min)
cis-1-Chloropropene oxide (*c*-CPO)		11
trans-1-Chloropropene oxide (*t*-CPO)		4.3
cis-1,3-Dichloropropene oxide (*c*-DCPO)		290
trans-1,3-Dichloropropene oxide (*t*-DCPO)		300
Trichloroethylene oxide (TCEO)		1.3
Tetrachloroethylene oxide (PCEO)		12

tions, the medium was removed, the cells were washed with PBS, and the appropriate dilution of the test chemicals was added to the cells in 4 ml PBS. The PBS was removed after incubation at 37°C for 30 minutes, the cells were washed, and fresh complete medium was added. After 5 more days of incubation, the cells were washed with PBS, fixed, and stained with Giemsa. Colonies (minimum 2-mm in diameter) were counted to determine cloning efficiency and examined for morphologic transformation. Morphologic transformation is defined as an altered colony morphology consisting of crisscrossing and piled-up cells not observed in controls (*15*). The transformation frequency is calculated relative to surviving colonies and to the initial number of cells plated. A total of 12 dishes were used at each concentration.

RESULTS AND DISCUSSION

The advantage of using the quantitative hamster embryo culture model to study carcinogenesis is that the effect of physical and chemical agents can be observed at the target cell level without the complications of host-modifying factors. Whereas the morphology of colonies formed by nontreated hamster embryo cells consisted of oriented cell arrangements, colonies classified as transformed by the chloroalkene oxides were similar to those induced by carcinogens such as benzo[*a*]pyrene. The relevance of morphologic transformation to neoplasia is that greater than 90% of transformed hamster cell colonies result in transformed cell lines that produce tumors when injected into nude mice or newborn hamsters (*16*).

All six chloroalkene epoxides induced morphologic transformation and cytotoxicity in hamster embryo cultures (table 1, text-fig. 2). The transformation results obtained with different concentrations of *c*-CPO, *t*-CPO, TCEO, and PCEO were consistent with the linear dose response. On a molar basis the most effective compounds were *c*-DCPO and *t*-DCPO, which induced transformation in the range of 0.01 m*M*; the least effective compounds were TCEO and PCEO, which required more than 1.0 m*M* (text-fig. 2). Although in all cases the cells were exposed to chemical for 30 minutes, the effective reaction time probably varied because of the instability of some compounds. This is especially true for TCEO and *t*-CPO, which have half-lives of less than 5 minutes. With *c*-DCPO and *t*-CPO the decrease in the transformation frequency at the higher concentrations is a reflection of the increased toxicity; in all cases, however, transformation was observed even when toxicity was less than 25% (table 1). Consideration of transformation on the basis of the number of cells seeded (absolute number) confirms the inductive nature of transformation by the chloroalkene oxides (table 1).

In general, the more stable the compound, the lower the concentration required; *c*-DCPO and *t*-DCPO, which are at least 25–30 times as stable as the other compounds, induced transformation at a hundredfold or lower concentrations. Therefore, in this assay, some relationship between chemical stability and biological potency exists. However, the *trans*-isomer compared to the *cis*-isomer induced twofold more transformation (absolute number) at the same concentration with similar toxicity (table 1) even though the half-lives of the *trans*-isomer and the *cis*-isomer were essentially identical (text-fig. 1). Moreover, tenfold more PCEO was required to induce transformation than was required with *c*-CPO even though the half-lives of PCEO and *c*-CPO are the same, which suggests that the bulky chlorine atoms on PCEO limit its ability to interact with DNA. Therefore, half-life alone does not correlate with carcinogenic potency.

The effects of these same chloroalkene oxides in bacterial systems have recently been reported (*10*). The mutagenicity of all six epoxides in *Salmonella typhimurium* TA 1535 and in *Escherichia coli* WP-2 UV light-sensitive gene A and their effects in *E. coli* (DNA polymerase A$^-$/DNA polymerase B$^+$) were determined in the absence of metabolic activation and compared to the transformation results (table 2). All six compounds induced cytotoxicity in *E. coli* and *S. typhimurium*; again, *c*-DCPO and *t*-DCPO were the most potent. PCEO was effective in only the *Salmonella* system, whereas TCEO induced no mutations in either system. Therefore, except for TECO, there is a reasonable quantitative agreement between the bacterial tests and the in vitro hamster transformation assay in terms of biological effectiveness of these chloralkene epoxides. Possibly, the highly unstable TCEO might have been inactivated before it reached most of the cells in the mutagenesis assays because treatment was performed on a concentrated number of cells suspended in culture medium; in the hamster embryo cell assay, the cells were treated in the presence of PBS.

Table 1.—*Transformation and survival of Syrian hamster embryo cells treated with diverse chloroalkene oxides*[a]

Compound	Dose, m*M*	Percent survival	Total transformed colonies	Average transformations/cells seeded, ×10^3
Acetone		100 (29)[b]	0	
c-CPO	0.11	110	4	1.1
	0.27	94	5	1.4
	0.55	90	6	1.7
	1.1	50	12	3.3
t-CPO	0.22	96	0	—
	0.55	78	2	0.56

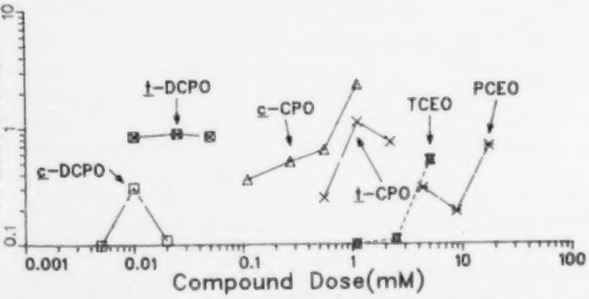
	17.1	70	5	1.4

[a] Plastic dishes (60 mm) were seeded with 300 cells from a secondary culture with irradiated hamster cells (6×10^4) for a feeder, grown for 2 days, and incubated with the test chemical in PBS in the absence of growth medium for 30 min at 37°C. Cells were washed, fed again, and incubated for 7 days after which colonies were stained, counted for survival data, and scored for morphologic transformation. Twelve dishes were used for each treatment.

[b] *Number in parenthesis* is the absolute cloning efficiency of solvent-treated cultures.



Text-figure 2.—Frequency of transformed colonies relative to survival and chemical concentration. The transformation frequency is total number of transformed colonies observed relative to the total number of colonies counted.

Table 2.—*Comparison of biological activities of diverse chloroalkene oxides*

Compound	Mutagenicity[a, b]		Genotoxicity:[a] *E. coli* pol A/pol A$^+$[b]	Transformation of hamster embryo cells[b]
	S. typhimurium TA 1535	*E. coli* WP-2		
c-CPO	++	+	+	++
t-CPO	+	+	+	++
c-DCPO	+++	+++	++++	++++
t-DCPO	+++	++	++++	++++
TCEO	−	−	++	+
PCEO	+	−	+	+

[a] *See* (*10*).

[b] Each plus represents one order of magnitude less compound (μg/ml) needed to produce a similar biological response. Maximum amount used is represented by a single plus. Minus indicates no effect at any concentration.

If these labile (text-fig. 1) putative proximate carcinogens are actual metabolites that survive detoxification, then the results provide an explanation for the carcinogenicity of the parental chloroalkenes. In fact, a mixture of *cis*-isomers and *trans*-isomers of *c*-CPO, as well as *c*-DCPO, TCEO, and PCEO induced carcinomas of the forestomach, or subcutaneous sarcomas, or hepatocellular carcinomas in mice (*17*, *18*). Although *c*-CPO, *t*-CPO, and *t*-DCPO have not been tested, our in vitro results indicate that they are also potential carcinogens.

Derivation of Transplantable 7,12-Dimethylbenz[*a*]anthracene-Induced Chicken Fibrosarcoma Lines: Differences in Metastasizing Properties and Organ Specificity[1,2,3]

J. E. Galton,[4,5] **B. Xue,**[4] **G. M. Hochwald,**[6] *and* **G. J. Thorbecke**[4,7]

ABSTRACT—Several transplantable 7,12-dimethylbenz[a]anthracene-induced SC chicken fibrosarcoma (CHCT-NYU) lines were studied for their ability to grow in internal organs after iv injection (artificial metastases) into 1- to 3-week-old chickens. Some tumor lines were recently derived, whereas others were studied after many serial subcutaneous transplantations. Striking similarities as well as differences were found between tumor lines' ability to grow in various organs. Artificial metastases were seen primarily in the stomach, pancreas, lungs, heart, and muscle, and occasionally also in the kidneys and in the liver. Agammaglobulinemic recipients showed more extensive organ involvement than normal recipients of the same age. Whole-body γ-irradiation also enhanced the incidence of artificial metastases, particularly in lungs. Antibody from the serum of a primary tumor-bearing host reduced the growth of the corresponding tumor in many organs. The metastatic pattern of line CHCT-NYU4 was a relatively stable property, since there was little difference in the internal localization of these tumor cells studied before and after 15 serial subcutaneous transplants. However, intravenous transplantation of tumor cells from line CHCT-NYU4 taken from the liver, lungs, and pancreas of a single recipient established sublines with changes in organ specificity. After a few such serial transplants of liver-derived tumor, a line was derived that grew virtually in the liver alone. A subline with preference for growth in lungs was also obtained, but its ability to grow in the pancreas persisted. A pancreas-derived tumor line also grew in the liver and lungs. Subcutaneous transplants of tissue fragments of the lung-derived tumor line caused the appearance of spontaneous metastases in lungs. The incidence of spontaneous metastases with the lung-derived line was much greater than that with the liver-derived line or with the original CHCT-NYU4 line.—JNCI 1982; 69:535–541.

In a previous study (*1*) with transplantable DMBA-induced fibrosarcomas, we showed that after iv injection into immature, histocompatible chickens, these tumors grew in a variety of internal organs. While we observed a similar organ distribution pattern with three tumor lines, we saw a higher propensity for growth in muscle with one line and a higher frequency of growth in lungs with another. The organ distribution of growth after injection of 2×10^7 CHCT-NYU4 cells (originally named SCFSIV) into 3-week-old unirradiated recipients was pancreas>stomach>heart>kidneys>lungs (*1*). Nonspecific stimulation of the immune system with *Corynebacterium parvum* inhibited fibrosarcoma growth in internal organs.

In studies on the metastatic ability of murine B16 melanoma and Abelson virus-induced lymphoma (*2-5*), repeated retrieval of metastases from a single organ, combined with periods of in vitro growth, led to variant lines with an enhanced tendency to metastasize to the organ of origin. Thus tumor lines were derived that preferentially grew in liver, brain, adrenals, ovaries, or lungs. The tendency of a transplantable Marek's lymphoma line to grow in the liver of SC chickens could also be enhanced by similar in vivo–in vitro procedures (*6*). In all these examples 5–10 repeated transplants and in vitro growth periods were needed before significant differences in metastatic properties were observed.

To test the generality of this phenomenon with respect to tumor cell type, we have attempted to derive organ-specific sublines from CHCT-NYU4 by serial intravenous transplants of tumor cell suspensions made from a tumor dissected from a single organ. The wide variety of organs in which these chicken fibrosarcomas can grow makes them an excellent tool for such a study. The present report shows that tumor lines with preference for growth in specific organs can readily be obtained in some cases within two serial transplants, without an intervening in vitro growth period. In addition, a subline is described with increased ability to metastasize spontaneously. The influence of some immunologic parameters on the sites of fibrosarcoma growth after iv tumor cell injection is also examined.

MATERIALS AND METHODS

Animals.—SC chickens, homozygous at the major histocompatibility B-locus (B2/B2), were used throughout the experiments. Chicken eggs were obtained from Hyline Poultry Farms (Dallas Center, Iowa). In some experiments, chickens received 300 rad of γ-irradiation from a ^{137}Cs source delivering 550 rad/minute (Isomedix, Parsippany, N.J.). BX was performed as previously described (*7*).

Tumor cells.—The fibrosarcomas CHCT-NYU1, CHCT-NYU2, and CHCT-NYU4 were derived from DMBA-induced (Eastman Kodak) primary tumors. These tumors grow only in SC chickens and were originally called "SCFS1,

SCFS2, and SCFS4," but they have been renamed according to a new nomenclature (*8*). CHCT-NYU1, the oldest tumor studied here, was shown to be rejected not only by B-locus-incompatible FP (B15/B21) chickens, but also, similarly to SC chickens, by RPRL lines 63 and 72 both B2/B2 (donated by the U.S. Department of Agriculture Regional Poultry Research Laboratory, East Lansing, Mich.). At the time of these experiments, CHCT-NYU1 (of female origin) was in its 60th monthly transfer in vivo, and CHCT-NYU2 and CHCT-NYU4 (of male origin) were in the 40th and 20th–40th transfers, respectively. The 2 other tumors, CHCT-NYU8984 and CHCT-NYU9136, more recently derived from DMBA-induced primary tumors, were in their 5th–10th transfer in vivo.

The tumor was dissociated into cell suspensions by incubation for 15 minutes at 37°C in a combination of 0.5% trypsin (1:250 hog pancreas; ICN Pharmaceuticals, Inc., Cleveland, Ohio) and 0.25% collagenase (Worthington Biochemical Corp., Freehold, N.J.) in 0.165 *M* DPBS (pH 7.2; Associated Biomedic Systems, Inc., Buffalo, N.Y.) containing 2% normal chicken serum (Flow Laboratories, Inc., Rockville, Md.). The resulting cell suspensions, 95% viable, were filtered through gauze and washed three times in DPBS. Only large typical tumor cells were included in the cell count. Contaminating smaller cells rarely exceeded 5%.

Antiserum.—Antiserum to CHCT-NYU8984 was obtained from the primary tumor-bearing chicken 8984, which received an injection of 8 mg DMBA 5 months previously. The 1:10 diluted serum was tested for the presence of antibody with the use of a triple-layer immunofluorescence technique (*9, 10*) and stained 40% of CHCT-NYU8984 tumor cells (Galton JE, Thorbecke GJ: Manuscript in preparation).

Treatment of tumor cells with antibody.—One milliliter of 2×10^7 CHCT-NYU8984 tumor cells was incubated on ice for 45 minutes with 1 ml of the antiserum. Without washing, 10^6 tumor cells were injected into 3-week-old γ-irradiated (300 R) chickens. The chickens were killed 14 days after receiving the tumor cell injection.

Experimental metastases.—In most experiments 3-week-old chickens received iv injections of $5–10\times10^5$ tumor cells in the wing web, and tumor growth in various organs was observed macroscopically 2–3 weeks later. The results were expressed as tumor incidence and TB or as GI to give both a semiquantitative and qualitative assessment of tumor growth. The presence of tumor in small nodules was verified microscopically after Formalin fixation and staining with hematoxylin and eosin. TB of each organ was estimated on a 1+ to 5+ scale: 1+=single to 3 small nodules, depending on the organ involved. For organs such as lungs, liver, and pancreas, complete infiltration or more than 15 nodules=5+; for stomach and kidneys, 10 nodules=5+; for heart and skeletal muscles of the leg, 5 nodules=5+. Tumor GI was calculated as the product of tumor incidence and the average TB for each organ. "Organ-specific" tumor lines were derived and maintained by serial intravenous passage of tumor cells taken from liver, pancreas, or lungs.

RESULTS

Experimental Metastasis Patterns of the CHCT-NYU4 Tumor

To minimize immunologic influences, we determined the pattern of experimental metastases of the CHCT-NYU4 tumor in 1-week-old chickens after iv injection of varying doses of tumor cells (table 1). The organ involvement was much greater than that found previously in 3-week-old recipients, but there was a similar distribution pattern, with 100% incidence of metastases in pancreas and stomach at a tumor dose of 2×10^5. A dose as low as 2×10^3 tumor cells still caused a significant involvement of stomach and lungs. The lowest dose injected, 2×10^2, did not result in any macroscopically detectable tumor growth within the 2-week observation period.

The pattern of organ distribution of tumor growth after iv injection of 10^6 or 10^7 CHCT-NYU4 cells was similar in unirradiated and γ-irradiated 3-week-old chickens (cf. text-fig. 1 and table 2). We observed much more tumor growth in internal organs with immunosuppressed (irradiated) chickens, and for this reason we used 3-week-old irradiated recipients in subsequent experiments.

Tumor Growth After iv Injection of Tumor Cells From Two Different Primary Tumors

The pattern of organ distribution of tumor growth after iv injection of CHCT-NYU4 tumor cells of the transplantable line was compared to that of 2 recently derived transplantable DMBA-induced fibrosarcomas. Tumor cells from CHCT-NYU8984 and CHCT-NYU9136 were injected into 3-week-old, γ-irradiated chickens, and internal tumor growth was determined (table 3). More than 70% of the recipients had tumor growth in the stomach, pancreas, lungs, and heart 3 weeks after the injection of CHCT-

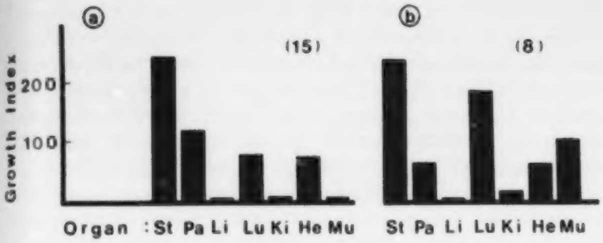
TABLE 1.—*Tumor incidence and TB in internal organs after iv injection of varying numbers of CHCT-NYU4 cells*[a]

No. of tumor cells injected	No. of chickens	Tumor incidence, %, and (TB)[b] in:						
		Stomach	Pancreas	Liver	Lungs	Kidneys	Heart	Muscle
2×10^5	4	100 (3.5)	100 (3.3)[c]	25 (1.0)[c]	75 (1.5)[c]	0	0	0
2×10^4	9	78 (3.2)	67 (1.1)	0	44 (0.8)	0	0	0
2×10^3	19	53 (1.1)	5 (0.1)	0	53 (1.2)	0	0	0
2×10^2	20	0	0	0	0	0	0	0

[a] Recipients were 1 wk old at time of tumor cell injection and were killed 2 wk later.

[b] Tumor incidence is expressed as percentage of animals with tumor in an organ; No. and size of nodules per organ (TB) are averaged for all animals in the group. TB was estimated for each organ on a 1–5+ scale: 1+=single nodule; 5+=complete infiltration of organ with multiple nodules (*see* "Materials and Methods").

[c] The tumor-bearing organs in 1 of these recipients were used for the derivation of organ-specific transplant lines.



TEXT-FIGURE 1.—Tumor growth after iv injection of 10^6 tumor cells from the original CHCT-NYU4 line transplanted locally throughout period of subline derivation: a) at start of study and b) after ≈15 intervening serial local transplants. GI represents the average TB for recipients multiplied by the percentage of recipients with growth in that organ. Animals were 3 wk old and γ-irradiated (300 rad). No. of animals in group is given *in parentheses*.

NYU8984 cells. In contrast with the CHCT-NYU4 tumor cells, however, there was a much higher incidence of tumor involvement in the muscle, kidneys, and liver. Transplants of tumor cells obtained from the heart of recipients from the first serial transfer resulted in slightly increased tumor growth in heart and muscle (GI 139 and 65, respectively) and in decreased growth in other organs (table 3).

It proved difficult to establish experimental metastases from the CHCT-NYU9136 tumor. Injection of as many as 2×10^7 cells into 3-week-old irradiated chickens did not result in tumor growth (data not shown). The results shown in table 3 are those from an experiment in which 1-week-old chickens were killed 2 months after iv injection of 5×10^6 tumor cells. Chickens killed before this time showed no macroscopic tumor growth. There was preferential growth in the stomach (63%) and lungs (50%), and 25% of the recipients showed tumor growth in the pancreas and kidneys. There was no growth in the heart, muscle, or liver.

Effect of BX on Tumor Growth of CHCT-NYU4 Cells

To explore the influence of host immune responsiveness, we analyzed the effect of recipient BX on tumor growth. Unirradiated 3-week-old normal and BX chickens were given injections of 10^5–10^7 CHCT-NYU4 cells, and tumor growth was determined 15 days later (table 2). When as many as 10^7 cells were injected into normal chickens, tumor growth was found in the stomach, pancreas, and lungs. When the number of cells injected was 10^5, tumor growth was limited to the stomach. In contrast, BX chickens were much more susceptible to the induction of experimental metastases. At the highest cell dose injected, tumor growth was apparent in most organs of all recipients, and with as few as 10^5 cells, there was still tumor growth in the stomach, pancreas, lungs, and kidneys. We did not observe tumor growth in the liver in either normal or BX chickens.

Thus it appeared that BX resulted in an increase in the incidence of experimental metastases. It was not clear, however, whether this was due to the general poor health of BX animals or, in fact, to a lack of specific antibody production. To test the role of antibody in the control of experimental metastases more directly, we studied the effect of passively administered antiserum to CHCT-NYU8984 on tumor growth (text-fig. 2). CHCT-NYU8984 cells were incubated with the antiserum and injected at a dose that would give, in the absence of antiserum, a high incidence of experimental metastases. Tumor growth was apparent in all organs

TABLE 2.—*Effect of BX of host on tumor incidence and TB in internal organs after iv injection of CHCT-NYU4*[a]

No. of tumor cells injected	Pretreatment	No. of chickens	Tumor incidence, %, and (TB)[b] in:						
			Stomach	Pancreas	Liver	Lungs	Kidneys	Heart	Muscle
10^7	None	4	100 (2.8)	50 (1.5)	0	50 (0.5)	0	0	0
10^7	BX	4	100 (3.5)	100 (2.5)	0	100 (1.3)	25 (0.3)	100 (2.0)	100 (1.3)
10^6	None	4	75 (0.8)	0	0	25 (0.3)	0	0	0

10^5	None	4	100 (1.0)	0	0	0	0	0	0
10^5	BX	6	100 (1.7)	67 (0.7)	0	50 (0.5)	0	17 (0.2)	0

[a] Unirradiated 3-wk-old recipients.

[b] Tumor incidence was examined 15 days after tumor cell injection and is expressed as percentage of animals with tumor in an organ; No. and size of nodules per organ (TB) are averaged for all animals in the group. TB was estimated for each organ on a 1–5+ scale: 1+=simple nodule; 5+=complete infiltration of organ with multiple nodules (*see* "Materials and Methods").

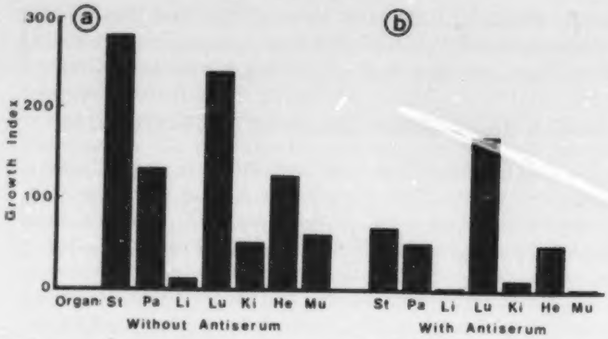
TABLE 3.—*Patterns of organ distribution of tumor growth after iv injection of tumor cells from 2 different primary tumors*[a]

Primary tumor source: Chicken	No. of serial iv transplants	No. of tumor cells injected	No. of chickens	Tumor incidence, %, and (TB)[b] in:						
				Stomach	Pancreas	Liver	Lungs	Kidneys	Heart	Muscle
8984	1	$2–5\times10^6$	14	93 (2.5)	79 (1.4)	21 (0.3)	71 (1.6)	43 (0.6)	71 (1.6)	50 (0.6)
	2+3[c]	5×10^5	13	62 (2.3)	69 (1.6)	0	31 (0.8)	23 (0.6)	77 (1.8)	54 (1.2)
9136	1	5×10^6	8	63 (0.8)	25 (0.5)	0	50 (1.6)	25 (0.8)	0	0

[a] Primary tumors were taken from 2 carcinogen-injected chickens. Recipients of tumor 8984 showed growth in internal organs 3 wk after transfer, but recipients of 9136 showed no tumor growth until 2 mo after transfer. Recipients were 3-wk-old, γ-irradiated (8984) or 1-wk-old chickens (9136).

[b] Tumor incidence is expressed as percentage of animals with tumor in an organ; No. and size of nodules per organ (TB) were averaged for all animals in the group. TB was estimated for each organ on a 1–5+ scale: 1+=single nodule; 5+=complete infiltration of organ with multiple nodules (*see* "Materials and Methods").

[c] Heart tumor from primary transplant recipient used as donor cells.



TEXT-FIGURE 2.—Growth of 10^6 iv injected cells from tumor CHCT-NYU8984 after preincubation with a) normal chicken serum, or b) antibody-containing serum from primary host chicken 8984. ≈1 ml of serum was injected together with the tumor cells into 3-wk-old γ-irradiated (300 rad). Recipients, and the tumor growth was determined 2 wk later. No. of recipients was 9 from group a) and 3 from group b).

observed after iv injection of untreated CHCT-NYU8984 cells. Although the number of animals given injections of antiserum-treated CHCT-NYU8984 cells was small, there was a decrease in the tumor incidence and TB in most organs. The absence of growth in the muscle was striking, particularly in view of the previous experiments (table 3) in which animals that received as few as 5×10^5 untreated CHCT-NYU8984 cells also showed a more than 50% tumor incidence in this organ.

In an additional experiment (data not shown), iv injection of antibody to CHCT-NYU4 with corresponding tumor cells also resulted in a decrease in tumor growth in the muscle (GI=4 vs. 105), but there was little effect on the growth in other organs.

Development of Organ-Specific Tumor Lines

Text-figure 1A shows the extent of tumor growth, expressed as GI, of 10^6 "parent" CHCT-NYU4 cells after injection into 3-week-old irradiated chickens. There was a similar distribution of tumor growth compared to that found previously in unirradiated recipients. Thus the stomach, pancreas, and heart showed GI of 250, 120, and 70, respectively. The low dose of irradiation, however, caused an increase in tumor growth in the lungs (GI=80), and an occasional bird also showed growth in the liver, kidneys, and muscle. After approximately 15 additional serial subcutaneous transplants, tumor growth was reexamined with the use of the same protocol at the termination of this study (text-fig. 1B). The organ distribution was not significantly different from that observed at the start of the study, although the extent of organ involvement had increased for lungs (GI=180) and muscle (GI=100) and decreased for pancreas and heart (GI=60). Again, there was an occasional chicken that exhibited growth in the liver and kidneys. Thus the ability of the parent line to localize and/or to grow in internal organs was a relatively stable property.

Although CHCT-NYU4 cells rarely showed tumor growth in the liver, one of the recipient chickens (table 1) showed tumor growth in liver, lungs, and pancreas. It was from this chicken that we attempted to develop tumor lines with organ specificity by repeated serial intravenous transfers of tumor cells taken from these organ sites. After as few as two to three serial intravenous transplants of liver-derived tumor, a different growth pattern was obtained, and by the fourth to fifth transplant of this subline 87% of recipients had extensive growth in the liver (GI=180), whereas the incidence of both pancreas and lung involvement was only 17% (GI=40) (text-fig. 3). After nine transplants, the liver line formed multiple nodules in the livers of virtually all of the recipients. In many chickens, livers were almost replaced by tumors within 2 weeks after injection of the tumor cells, whereas there was only sporadic growth in other organs.

This liver specificity was maintained over many transplantations. Even when the liver-specific tumor was transplanted from wing web to wing web several times before it was again injected iv, it maintained its specificity for growth in liver. In this experiment, 10^4 liver-line tumor cells, injected iv into 2-week-old γ-irradiated recipients, grew in

TEXT-FIGURE 3.—Tumor growth of the three sublines derived from CHCT-NYU4 by serial intravenous transplantation of 10^6 tumor cells taken each time from lungs, liver, or pancreas. The numbers of serial intravenous transplants are given at the *bottom*. GI is represented as in text-fig. 1. All recipients were 3 wk old and γ-irradiated (300 rad). No. of recipients is given *in parentheses*.

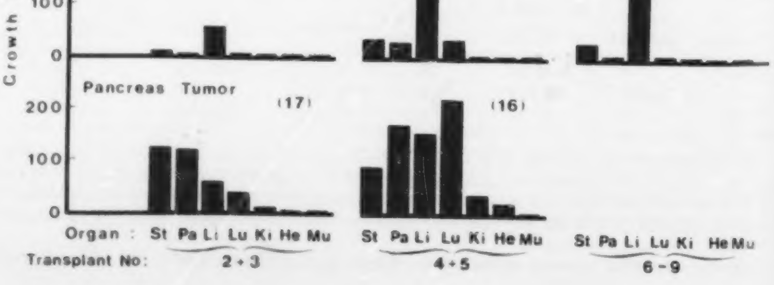


TABLE 4.—*Metastatic potential and organ specificity of transplantable CHCT-NYU tumor lines*[a]

Tumor line	Method and site of inoculation	Total No. of recipients	Percent of recipients with tumors in:				
			Stomach	Pancreas	Lungs	Liver	Heart
CHCT-NYU1	10^6 cells in both wings	45	0	0	0	0	0
CHCT-NYU2	10^6 cells in both wings	65	6.1	4.6	3.1	0	1.5
CHCT-NYU4	10^6 cells in both wings	70	10.0	7.1	1.4	0	0
CHCT-NYU4 "liver"	Fragments in wings	28	0	0	0	7.1	0
CHCT-NYU4 "lung"	Fragments in wings	40	0	7.5	47.5	2.5	0

[a] Chickens were 1 wk old and were γ-irradiated prior to receiving tumor fragment injection or 2 wk after injection of tumor cells in the wings.

67% of the receipients' livers (GI=89) within 3 weeks. Among the other organs only the lung showed a small amount of tumor growth (GI=7; incidence 22%). In an additional study, iv injection of 10^9 killed *Corynebacterium parvum* organisms, just prior to injection of the liver subline, prevented all tumor growth in 9 of 10 animals (data not shown). In the remaining animal, only a single liver nodule was found compared to massive TB in the livers of control animals (GI=160).

Five serial intravenous transplants of lung-derived tumor cells resulted in 95–100% involvement of both lungs and pancreas (GI=200), with much less growth in liver. After the ninth passage, the lung-derived tumor cells grew in 100% of the recipients' lungs, and to a much lesser extent in the stomach, pancreas, heart, and liver (text-fig. 3). After further transplantation (data not shown) the lungs remained the primary target for this tumor line, and the incidence of concomitant growth in the pancreas did not change.

Serial transplantation of pancreas-derived tumor did not result in similar organ specificity: GI of the pancreas, as well as of the lungs and liver increased, but that of the stomach decreased (text-fig. 3). After five passages, transplantation of this subline was discontinued.

Metastatic Potential and Organ Specificity of Transplantable CHCT-NYU Cell Lines

An attempt was also made to determine whether the transplantable organ-specific CHCT lines could metastasize spontaneously. One-week-old chickens were inoculated with CHCT-NYU1, CHCT-NYU2, and CHCT-NYU4 tumor cells in both wing webs, irradiated on day 14, and dissected 2 weeks later (table 4). There was no tumor growth in any organ of the 45 chickens given injections of CHCT-NYU1 cells, although previous studies had shown extensive growth of this tumor in internal organs after iv injection of tumor cells (*1*). After injection of CHCT-NYU2 and CHCT-NYU4 tumor cells in the wing webs, a small number of chickens did exhibit metastases, primarily in the stomach and pancreas, and occasionally in the lungs and heart. The possibility, however, that a small number of tumor cells was inadvertently injected intravascularly could not be excluded. This could explain the formation of these "spontaneous" metastases, because as few as 2,000 iv injected CHCT-NYU4 cells resulted in tumor growth in the stomach, pancreas, and lungs of 1-week-old chickens (table 1).

To minimize direct cell entry into the blood, we inoculated small washed fragments, rather than cell suspensions, of organ-specific tumors into both wing webs of 1- to 2-week-old γ-irradiated chickens (table 4). Almost 50% of the 40 chickens given injections of lung subline tumor fragments showed tumor growth in the lungs. Occasionally, a few tumor nodules were also found in the pancreas (8%) and liver (3%). After wing web inoculation of the liver subline tumor fragments, metastases were confined to the liver, but these occurred in only 8% of recipients. Tumor invariably grew progressively in the wing webs of both liver- and lung-line recipients.

The metastatic potential of these lung- and liver-specific sublines was further tested by ip injection of tumor cells into 2-week-old chickens (not included in tables). Four weeks later, 78% of the 9 birds given injections of liver subline tumor cells showed extensive growth in the liver (GI=250). There was no evidence of growth in any other organ. The lung subline exhibited some growth in the liver, but much less than the liver line, and metastasized to lung in 1 of the 4 recipients.

DISCUSSION

The patterns of artificial metastatic growth of the five randomly selected lines of DMBA-induced fibrosarcomas, studied previously (*1*) and in the present report, show some striking similarities as well as differences. The stomach and pancreas are common localization sites for all five tumor lines, and three of these lines also show heart and skeletal muscle as major sites. Lung localization was very much enhanced by irradiation of recipients similarly to many mammalian tumor systems (*11*). Immunologic incompetence of recipients resulting from BX (agammaglobulinemia) also greatly increased tumor growth in lungs and in some cases in heart and muscle. This observation suggests an antibody role in the limitation of tumor growth in internal organs, which is in agreement with the finding that passively acquired antibodies obtained from the primary host abolish the growth of line CHCT-NYU8984 in the muscle. Of the five tumor lines studied, only one (CHCT-NYU2) exhibited preferential growth in the liver (*1*), and another (CHCT-NYU8984) grew well in the kidneys.

It seems likely that patterns of metastases are influenced by the nature of the tumor cells. Only a few studies on transplantable tumors in chickens are available for comparison (*6, 12*). These studies concern Marek's disease T-cell lymphoma, and the patterns of lymphoma localization include the ovaries, the kidneys, and the liver. They are thus different from those of fibrosarcomas reported in the present study. Comparison of lymphomas derived from cells that normally migrate, with fibrosarcomas may not be appropriate. Studies of human soft tissue sarcomas show preferential metastatic sites, primarily the lung (*13*).

Organ-specific sublines were obtained rapidly from tumor line CHCT-NYU4 in the present study. Further experiments are needed to determine whether adaptation to an organ during growth in that organ is involved in this phenomenon, or whether there is a preexisting heterogeneity with respect to organ preference in CHCT-NYU4 at the time of intravenous transplantation. Studies by Fidler and Kripke (*14*) on B16 melanoma in mice showed heterogeneity of the tumor itself to be a major factor in causing variation in metastatic behavior. Chow and Greenberg (*15*) showed that heterogeneity of a lymphoma clone was generated within a short time in the syngeneic host. In addition, Nicolson and Custead's recent finding (*16*)—that forcing a tumor to grow in the lungs does not improve its ability to produce experimental metastases on the same site—also refutes the idea of organ adaptation. The chicken lymphoma system studied by Shearman and Longenecker (*17*), in which liver metastases could be prevented by preincubation of tumor cells with a monoclonal antibody without an effect on metastases in other sites, strongly supports the concept of organ-specific receptors.

In the present studies with chicken fibrosarcoma, a liver-specific tumor line was readily derived. The ability to grow in pancreas was never completely dissociated from growth in the lungs. Selection for growth in lungs resulted in a variant that grew best in lungs, but it still metastasized to the pancreas. Metastases to heart and skeletal muscle also appeared to be linked, but no attempt was made to separate tumor sublines metastasizing to these sites. Localization of metastases in muscle is rare in most mammalian systems studied thus far. This finding is attributed to the fact that embolic tumor cells are trapped in arterioles and do not reach the capillary beds in the muscle, thyroid gland, and spleen (*18*).

Hypotheses such as "favorable environment of the soil" (*19*), which causes preferential tumor growth in a given organ, and existence of cell surface receptors, which (*12, 20*) cause selective retention of tumor cells in organ sites, have been put forth as explanations for organ specificity of metastasis (*21*). Some preliminary experiments have been performed to analyze which possibility might be applicable to the present results. No evidence for organ-specific receptors on the tumor cells could be found, since attachment of tumor cells from the liver and lung sublines to sections of various organs (*22*) was not different from controls. Moreover, when cells of the liver-adapted line labeled with ^{125}I-labeled uridine deoxyriboside were injected iv, a much higher percentage of the labeled cells was seen in the lungs than in the liver during the first 24 hours, even though the tumor rarely grew in the lungs.

There are many factors that influence the ability of tumors to metastasize spontaneously (*21, 23*). In our studies, the lung-adapted line had definite metastatic properties. Lung metastases also arose when tumor pieces, rather than cell suspensions, were used for injection in the wing web to minimize accidental iv injection of viable tumor cells. The incidence of spontaneous metastases of the liver-specific sublines was much lower. Since the liver line grows very well in liver after iv or ip injection, these findings show that a major factor that determines the difference between the metastatic abilities of the liver and lung localizing lines may reside in their relative capacity to get into the circulation. However, if only a few cells gain access to the circulation, the first organ encountered will be the lung. Therefore, the metastatic capacity of cells able to grow in the lungs will be detected more readily than that of cells, which according to the "soil hypothesis," prefer to grow in the liver. Further studies are needed to analyze some of the possible characteristics associated with these metastatic properties (*24–33*).

The present results show that relatively stable transplantable lines with a high degree of organ preference can be rapidly derived from the DMBA-induced chicken fibrosarcomas. They suggest that this tumor model provides an excellent tool for further study of this phenomenon.

Meeting Highlights

Cytogenetics and Somatic Cell Genetics of Malignancy Workshop

This workshop on November 9–10, 1981 was sponsored by the Division of Cancer Cause and Prevention of the National Cancer Institute, National Institutes of Health, Public Health Service, U.S. Department of Health and Human Services, Bethesda, Md. The stated objectives were 1) to explore genetic areas that have potential interdisciplinary overlap with other areas of cancer reseatch; 2) to bring together individuals in different disciplines, with the hope of stimulating and initiating collaborations; 3) to explore environmental and genetic interactions in the multifactorial origins of cancer; and 4) to identify areas to be examined for fundamental changes in carcinogenesis mechanisms and areas in which gaps in knowledge exist, for the purpose of making recommendations for future research.

In the three sessions of the 1.5-day workshop program, the interactions of the disciplines of cytogenetics, somatic cell genetics, molecular genetics, DNA repair, epidemiology, virology, chemical transformation, immunology, and molecular biology were discussed in relation to the mechanisms of carcinogenesis.

In the first session, the chairman Dr. Alfred G. Knudson indicated that genetic change related to cancer could be in the cancer genes or the accessory genes. The cancer genes may be dominant in cells and behave like' oncogenes or recessive genes that behave like the retinoblastoma or polyposis genes. Accessory genes can influence the rate at which changes occur in these cancer genes. Dr. Janet Rowley analyzed the cytogenetic findings in human leukemias and lymphomas, noting particularly that in Burkitt's lymphoma and chronic myelocytic leukemia more than one kind of chromosome translocation is characteristic, but that a common segment is found. Thus the Burkitt's aberration can be an apparently reciprocal translocation between chromosome 8 and any of chromosomes 14, 2, or 22. Segments of chromosomes 14, 2, and 22 code, respectively, for heavy, κ- and λ-chains of the immunoglobulins. Dr. Peter Nowell discussed chromosome abnormalities in leukemia and noted that stimulation of B-cells by terephthalate permits analysis of chromosome changes in chronic lymphocytic leukemia.

The rare but interesting cases of prezygotic chromosome lesions that predispose to cancer were discussed by Dr. Uta Francke. In retinoblastoma, band 13q14.3 is critical. In Wilms' tumor associated with aniridia, band 11p34 is deleted. This deletion was found in 18 individuals with aniridia, although some did not have Wilms' tumor. Dr. Louise Strong presented data on a family in which multiple offspring with retinoblastoma had the characteristic chromosome deletion. The parents of the affected individuals were carriers of a translocation that involves the same segment of chromosome 13. All four of the possible segregants of the translocation were found. Such a pedigree shows an irregular pattern of inheritance, with a 25% ration of affected children among the offspring carriers. This pedigree may be a paradigm for previously reported instances of so-called "premutation."

Dr. Mary Clare King discussed the linkage of a breast cancer gene with the gene for glutamate-pyruvate transaminase. Syndromes that characteristically show chromosome fragility were reviewed by Dr. James German. In xeroderma pigmentosum (XP) chromosome instability is seen after UV irradiation. In Werner's syndrome, chromosome mutations are observed, although breakage rates are not increased. In ataxia telangiectasia and Fanconi's syndrome, breakage and translocations are characteristic. In Bloom's syndrome, breakage and homologous chromosome exchange are prominent. Heterozygotes for ataxia telangiectasia have been shown by Dr. Michael Swift to be at increased risk for cancer. Inasmuch as such heterozygotes represent between 0.5 and 1.0% of the population, they could be making an important contribution to the incidence of cancer.

Dr. John Little discussed the in vitro repair to damaged DNA as a function of the interval of time after administration of a breaking agent to a confluent culture. A rapid component is concerned with repair of thymidine dimers and of chromosome aberrations, whereas a slow component is associated with DNA cross-links and sister chromatid exchanges. Dr. Malcolm Paterson noted that in the neurologic forms of XP, but not in the nonneurologic forms, nonphotoreactable sites are affected.

The second session of the workshop was chaired by Dr. Louis Siminovitch. In introductory remarks, he described some work in his laboratory by Dr. Irene Andrulis, who has been working with the gene system that controls asparagine synthetase. This gene was transferred into CHO cells by means of DNA. One of the transformed isolates contained highly elevated levels of the enzyme and a homogeneously staining region (HSR). The isolate, therefore, probably represents an example of gene duplication. Similar high levels of asparagine synthetase were achieved by the growing of wild type cells in increasing concentrations of albiizzin.

Dr. Warren Nichols described some of the consequences of transformation of human diploid cells with wild type and mutant simian virus 40 (SV40). Most of such cells undergo senescence similar to that of uninfected cells. Some mutants showed positive transformation when assayed in monolayer but were negative when tested in soft agar, indicating that the agar was more exigent and that possibly multiple events were involved. It also appears that SV40-transformed human diploid cells show increased sister chromatid exchanges (SCE) and chromosome anomalies at the same time as the T-antigen production increased. Dr. N. C. Popescu reported a correlation between SCE and morphologic transformation in Syrian hamster cells after treatment with benzo[*a*]anthracene, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, methyl methanesulfonate, and *N*-hydroxy-*N*-2-fluorenylacetamide. After X-irradiation, however, SCE was increased without morphologic transformation.

Dr. Susan Astrin described studies she made in collaboration with Dr. W. S. Hayward on the activation of cellular genes by means of promoter sequences. In earlier studies they had demonstrated such activation for the *myc* gene in tumors in an avian system. Inasmuch as humans also carry the *myc* gene, Dr. Astrin and Dr. Hayward explored its possible activation in human acute lymphocytic leukemia (ALL), chronic lymphocytic leukemia (CLL), and Hodgkin's disease. By blot hybridization analysis with the use of a *myc* DNA probe, elevated levels of the *myc* gene RNA were found in some of the CLL, ALL, and Hodgkin's disease patients. Dr. E. Skolnik presented some examples of cellular gene activation by promoters. He also described examples in which the cellular *onc* gene had been amplified.

Dr. R. Weinberg reported on his recent studies on transformation, in which he used DNA from a variety of murine and human tumors. Examination of the restriction enzyme sensitivity of various tumor-derived DNA's indicated that the same gene may be activated in each tissue type. Dr. Weinberg has also been cloning some of these genes and examining their sequence interrelationships. Two different bladder carcinomas seem to have activated the same gene sequence. In the case of a colon carcinoma, the gene was found to be present in normal cells, supporting the concept of activation of sequences during carcinogenesis.

Dr. B. D. Crawford is involved in studies that examine the multistep nature of carcinogenesis as indicated by the successive appearance of new cancer phenotypes. Dr. P. Lalley, by analysis of XP human–murine cell hybrids, has been attempting to map the genes involved in UV radiation repair. The present data support the concept that chromosomes 3 and 8 are involved.

In the third session, chaired by Warren W. Nichols, Dr. Michael Potter discussed the differential susceptibility of various mouse strains to plasmacytoma induction by injections of pristane. BALB/cAn mice are quite susceptible to this procedure, whereas most other mouse strains are resistant. Susceptibility and resistance genes differ within strains. BALB/c pristane-induced plasmacytomas all showed translocations involving chromosome 15 and either chromosome 6 or 12. Chromosome 6 and 12 breakpoints are associated with regions that code for Igκ and Igλ complex loci, respectively, with the breakpoint on chromosome 15 the same in both translocations. Dr. June Biedler commented on the high frequency of trisomic chromosome 15 observed in mouse leukemias.

Dr. Robert Schimke discussed the loss of cellular restraint by increased synthesis of specific cellular proteins. One of the mechanisms of the increased protein production is gene amplification, which has been associated with the acquisition of drug resistance, reversion of auxotrophy, and in embryonic development. Cytogenetically, HSR's and double minute chromosomes (DM) have been associated with the phenomenon, and amplified genes have been mapped to these areas. Dr. June Biedler and Dr. Gloria Balaban reported on the occurrence of HSR's and DM in clinical and experimental tumor material.

Dr. T. Mohandas discussed gene regulation by methylation of DNA. The modification of DNA that methylation produces has been proposed as a mechanism of X-chromosome inactivation. Use of 5-azacytidine results in hypomethylation of DNA. The addition of this chemical to a mouse–human hybrid cell that contained the inactive X-chromosome as the only human chromosome resulted in the reactivation of human hypoxanthine phosphoribosyltransferase (HPRT) at a frequency of 1 in 700 cells in comparison to a frequency of 1×10^{-6} in untreated cells. DNA isolated from cells with a reactivated chromosome X was competent in a transformation assay with an HPRT line, demonstrating that the changes were at the DNA level. Dr. O. J. Miller described studies with rat hepatoma cells containing a large HSR associated with ribosomal gene amplification. Staining of nucleolar organizing region demonstrated that only a few of these genes are active, and antibodies against methylcytosine reacted with the amplified genes.

Following session 3, a general and very active discussion period was held concerning the greatest opportunities for progress. There was unanimity regarding the importance of interactions and communications between disciplines. Means of communication that were discussed included meetings similar to the one just completed, Gordon conferences, newsletters, and listings of accessible biologic materials, such as the listing of available recombinant DNA probes that Dr. Francke and Dr. Skolnick are in the process of compiling. Making available materials that are standardized but usually not readily obtainable can stimulate research.

Communication and interactions are the keys to interdisciplinary collaboration, as illustrated by at least four proposed collaborative efforts that resulted from the current meeting. Interdisciplinary training programs and task force approaches were also suggested. The need for initial support in new areas and in interdisciplinary areas and the development of lists of available biologic supplies, as mentioned above, were considered to be especially important in assuring progress. In more than 25 letters and phone calls after the conclusion of the workshop, other important areas were suggested—too many to be recounted here.

Brief Summary of the Third Joint Meeting of the United States–Japan Cooperative Cancer Research Program on Cell Interactions and Cancer

The third joint meeting of the Cellular and Molecular Biology Sub-area of the United States–Japan Cooperative Cancer Research Program was held in Kyoto from November 5–7, 1981, on the subject of cell interactions and cancer.

The 17 participants, 5 from the United States and 12 from Japan, were of various backgrounds related to cell interaction and/or cancer. The presentations covered a diverse series of topics ranging from cell-to-cell adhesion in the cellular slime molds to studies of the pathology of human cancer. In spite of this wide diversity of topics, the discussions were lively, reflecting the commonality of interests of the participants and the common tools of their research effort.

In the first two sessions cell adhesion was discussed in relation to morphogenesis and differentiation. A number of cellular systems were discussed in which the cell surface changes in a systematic way during development. Included in these discussions was extensive work on the cellular slime mold (Ikuo Takeuchi, Samuel Barondes) as well as studies of cell lineage and the maintenance of the cell proportions in differentiation mutants of hydra (Tsutomu Sugiyama). Cell adhesion also influences the growth in differentiation of cells, as has been demonstrated in fibroblasts (3T3 cells and Schwann cells) under culture conditions (Luis Glaser). In these and other simple systems, analysis of factors involved in cell–cell interaction appears promising. Although several cell-adhesion molecules have been identified in several systems, it was recognized that we are far from understanding the molecular events regulating cell behavior and the precise way in which cell surface molecules participate in these events. This is true not only for the complex phenomena discussed at the meeting but also for the interaction of more defined cell molecules, such as hormones, with the cell surface. Before any generalizations can be made, each of these systems will have to be examined in greater detail and at a more detailed molecular level than has been achieved so far.

The neuronal connection, a phenomenon in which cell recognition is potentially involved, was discussed in particular in relation to retino-tectal projection by Hajime Fujisawa. Dr. Fujisawa followed the developmental pathway of retinal fibers that had been labeled with horse-radish peroxidase and succeeded in showing for the first time that the pathway by which these axons reached their target cells in the tectum involves a great deal of trial and error in search rather than a totally directed transit to the cells. These elegant experiments served to rule out a number of currently popular models by which the retino-tectal connections are made and strongly suggest that trial and error is at least in this instance a major mechanism for reaching a correct target. The precise molecular mechanism by which the growth count of an axon differentiates among surface molecules to reach a preferred adhesion site is one of the more exciting puzzles in the cell-adhesion field.

Strong evidence was given that cell surface receptors do play decisive roles for cell interaction and hence for normal development. Specific lymphocyte homing in the lymphoid organ of the frog was demonstrated (Shin Tochinai), and such homing of migratory cells was shown to be regulated in mice by the binding of lymphocytes to high endothelial venule and organ-specific surface cells via genetically restricted receptors (Irving Weissman).

The third and fourth sessions dealt with phenomena more directly related to cancer. The differentiation of tissue mast cells and growth of leukemia cells in vitro were reported to depend on microenvironment (Yukihiko Kitamura, Hiroshi Hiai). Since collagen and fibronectin are of primary importance as extracellular microenvironments in situ and decrease after malignant transformation, studies on the structure and regulation of these molecules are of interest. Binding sites for collagen, heparin, and other macromolecules have been precisely mapped on fibronectin molecules (Kenneth Yamada). The structure of a type I collagen gene was analyzed and shown to have a unique regulatory region containing three large, inverted repeats; it was suggested that hypothetical regulatory proteins that interact with this region may be modified in transformed cells (Ira Pastan).

In the discussion of adhesion of transformed cells, alteration of adhesion properties of in situ cancer cells was demonstrated as well as in vitro cell lines (Hideo Hayashi, Masatoshi Take-ichi, Hideko Urushihara). Malignant types of gastric carcinoma constituted of dissociative cells were examined with the use of electron microscopy and [^{3}H]-thymidine autoradiography. [^{3}H]thymidine-labeled growing cells were shown to be abnormally distributed in cancerous areas because of decreased adhesiveness and peculiar motility (Setsuya Fujita).

The meeting was a mixed demonstration of clear molecular study and of complicated phenomena in higher organisms. This impression no doubt summarizes the present status of the study of cancer at the cellular level.

Our overall evaluation of this meeting was that it was an excellent exchange of science by professionals with varying approaches. There were ample opportunities both during the formal presentations of papers and in relaxation times for broad-ranging discussions among the participants, and these appeared to be utilized fully. It was a productive 3-day period for all involved.

The public symposium that followed at the close of the "formal" meetings attracted an audience of 100, some from as far away as Nagoya and Tokyo. The audience was made up of professionals and interested students. This symposium was entitled simply "Cell Interaction," and four speakers from the United States presented their views and work during the 3-hour session. This type of sharing of knowledge is perhaps too rare among the generations, and the fact that it was so well attended would appear to testify to the fact that more such presentations would be welcomed.

Corrections

May 1982, vol 68, No. 5

In "Comparison of In Vitro and In Vivo Effects of Thymidine on L1210 Leukemia in Mice," by Daniel S. Zaharko and Lori M. Ramonas, page 878, the last sentence in the legend to text-figure 5 should read: N/N_0=No. of cells at time=t/No. of cells at time=0 (*not* N/NO=No. of cells in drug-treated tubes/No. of cells in control tubes).

NCI Monograph No. 58

In "Carcinogenic and Mutagenic N-Substituted Aryl Compounds," NCI Monograph No. 58, page 47, the sentences beginning in the second line of the right column should read:

> Smaller molecular weight arylamines have lower overall carcinogenic and oncogenic effects than do larger molecules. When the amino group is alpha to an anellated ring position in a polycyclic arylamine, such as 1-NA or 2-BPA, current views are that such chemicals are not carcinogenic because they cannot undergo the required biochemical N-hydroxylation reaction to a sufficient extent.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Temporomandibular Joint——Pain and Dysfunction Course

The University of Rochester Medical Center School of Medicine and Dentistry and Strong Memorial Hospital will sponsor this course to be held at the Plaza Hotel, New York City, on September 24–26, 1982. This course is designed for persons involved with diagnosis, assessment, and treatment of temporomandibular joint (TMJ) disease. Course offerings will include clinical evaluation and arthrographic and differential diagnosis of the disease, use of contrast media and plain film techniques, and both surgical and nonsurgical methods of managing TMJ pain and dysfunction. Coverage will also extend to pathophysiology of mandibular dysfunction, myofacial pain dysfunction syndrome, and degenerative joint disease.

Accreditation approved AMA Category I credit for 16 hours; approved by the ADA Continuing Education Registry for 16 hours. For additional information please contact Educational Resources Associates, Inc., P. O. Box 369, Brookline, Massachusetts 02146 (telephone: 617-738-8859).

Second Annual International Symposium on the Clinical Applications of Cardiopulmonary Imaging

This 4-day cardiopulmonary course, to be held at the Hyatt Lake Tahoe, Lake Tahoe, Nevada, on September 29–October 2, 1982, is designed for all practitioners who desire a comprehensive "patient-oriented" learning experience in the newest cardiopulmonary imaging techniques. The course will update and refine assessments of the different imaging techniques and their application to diagnosis and management of patients with cardiopulmonary diseases.

AMA Category I accreditation has been approved for 24 hours. Additional information on tuition and registration is available from Educational Resources Associates, Inc., P. O. Box 369, Brookline, Massachusetts 02146 (telephone: 617-738-8859/8861).

Fifteenth Annual Malignant Disease Symposium

"Cancer and Nutrition—An Oncology Update" will be the subject of this symposium to be held at Chapel Hill, North Carolina, on October 22–23, 1982. Mounting evidence from current epidemiological and clinical research studies points to an association of nutritional excesses or deficiencies with certain cancers. This symposium has been organized to bring the most up-to-date information about these developments to practicing physicians, house staff, nurses, and health professionals involved with cancer patients.

For additional information please contact Dr. William D. Heizer, Cancer Research Center, Box 30, MacNider Building, The University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

Pediatric Radiology Course

Cambridge, Massachusetts, will be the site of this course to be held at the Hyatt Regency Hotel on November 1–3, 1982. This 3-day course, sponsored by the Department of Radiology of the Children's Hospital Medical Center and Harvard Medical School, will review the diagnostic and therapeutic imaging techniques employed in pediatric radiology, with emphasis on the application of these techniques to diagnostic problems in children.

Accreditation has been approved for 22 hours AMA Category I. For additional information please contact Educational Resources Associates, Inc., P. O. Box 369, Brookline, Massachusetts 02146 (telephone: 617-738-8859).

No. 59: Cancer Mortality in the United States: 1950–1977
    GPO Stock No.: 017-042-00161-7, $18.00 in the United States, Canada, and Mexico; $22.50 elsewhere

Copies are for sale **only** by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. When ordering, please be sure to make the check or money order payable to the Superintendent of Documents and include the title and stock number of the volume desired. Payment is required in advance.

Public Health Controversies—Food Safety Laws: Delaney and Other Dilemmas

The first in a series of national conferences on public health issues, sponsored by Boston University School of Public Health, will be held at the Capital Hilton in Washington, D. C., on September 23-24, 1982. The conference will be attended by the principal interests from the food industry, consumer groups, academia, the legal profession, and government. The program will focus on the latest efforts to frame workable food safety regulations; the projected legal implications of the passage of less stringent legislation, including questions of liability; the current and projected state of the art in food testing; and the public health and ethical issues raised by changing the current law.

For further information please contact Ms. Elizabeth M. Ollen, Conference Coordinator, Boston University School of Public Health, 80 East Concord Street, Boston, Massachusetts 02118 (telephone: 617-247-6201 or 617-247-6016).

HE 20.3161:

The cover illustrates biphasic inhibition of UV radiation-induced morphologic transformation of hamster fibroblasts by normal (naturally immune) spleen lymphocytes. Modulation of carcinogenesis at this early stage can result from immunoregulation of the immunologic hormone and anticarcinogenic lymphokine lymphotoxin. This study by Evans et al. (*see* paper on pages 737–740) dissects mechanisms of natural immunity that affect carcinogenesis.

Journal of the National
Cancer Institute

September 1982
Volume 69
Number 3

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols; *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40:2083–2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221–245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends, and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs*. Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3–10/Ann Intern Med 1979;90:95–99/Br Med J 1979;1:532–535/ or Lancet 1979;1:428–430).

Morbidity Versus Mortality

SIR: Our experience from Danish cancer registration since 1942 fails to support the opinions of Doll and Peto stated in their report to the U.S. Congress[1] in which they prefer mortality data, because trends in incidence data "are difficult to interpret because of the difficulty of allowing for the effects of more complete registration and of more screening."

In the beginning of their paper, the authors accept morbidity data from everywhere taken at face value for ages between 35 and 64 for subtraction of low rates from high rates to determine the amount of avoidable cancer. Nevertheless, in the end they find mortality data more reliable, doubting observations by the cancer registries with the longest records, those of Connecticut and upstate New York.

Doll and Peto further argue from an assumed bias caused by difficulty in delimitation of populations at risk and by changes in definitions and in the interest of physicians reporting—supposed to affect morbidity data more than mortality rates.

Some evidence to the contrary is the following: For the years up to 1950 we found age curves for upstate New York and Copenhagen closely similar for Hodgkin's disease, leukemia, and multiple myeloma,[2] and the similarity extends to a special study in leukemia morbidity in Brooklyn[2] and Hodgkin's disease around 1970. Is it credible that a bias in the estimate of the population at risk for upstate New York would result in rates similar to those for Copenhagen where the bias does not exist?

A bias from increasing inclusion of cases previously grouped as papilloma is suggested by Doll and Peto for urinary bladder tumors, although for once they accept for this site the increasing morbidity rates as more reliable than the decreasing mortality rates for the United States. However, morbidity rates for Denmark, where papillomas have always been included, show an increase in morbidity rates of the same pattern as that seen in Connecticut, and not too different from that of upstate New York.[3-6]

The influence on morbidity rates from screening has been analyzed for breast cancer on Danish data[2] without explaining the steady increase in morbidity, whereas screening for cervical carcinoma in situ appears to have turned an increase in invasive carcinoma into a decrease, both in Copenhagen and Connecticut.[3]

In contrast, U.S. mortality data compared with hospital data for the same persons have recently shown deficits up to 43.8% as reported for rectal cancer.[7]

While there is every reason to avoid exaggeration of the obvious gradual increase of many nontobacco cancers,[8] it is still more important not to disregard this trend or the valuable contributions to cancer registration from Connecticut and upstate New York.

[8] A diagram (text-fig. 2) in the July 1981 issue of JNCI (vol. 67, p. 9) failed to show the latest Danish rates increasing for male lung and prostate cancers.

SIR: Drs. Clemmesen and Nielsen appear to have misunderstood our main purpose, because most of their criticisms are not relevant to it. In our review of the causes of cancer in the United States,[1] we needed to examine the trends in U.S. cancer onset rates, and for this purpose two chief types of data (mortality and morbidity) were available, neither of which is wholly reliable.

Mortality data are in error when the underlying cause of death is miscertified, which it quite often is. Trends in the accuracy with which causes of death are certified can therefore produce artifactual trends in recorded mortality, either for cancer as a whole or for particular types of cancer.

Morbidity data derive from cancer registries that seek to record all cases of cancer that occur among the residents of a defined geographic area, such as the State of Connecticut or upstate New York. These may be in error not only when the cancer is misdiagnosed but also when a cancer that has been diagnosed is not reported. The likelihood that a life-threatening cancer will never be diagnosed is small, but the prevalence of asymptomatic, undiagnosed lumps in an old person that would be described as "cancer" and registered if they were biopsied and examined histologically can be large. For example, in a special study of the prostate glands of 70-year-old men dying of unrelated diseases, 25% were found to have cancer,[2] although the cumulative incidence of prostate cancer that is diagnosed clinically by the age of 70 is only 3%. In other words, about 90% of prostate cancer in 70-year-old men is at present undiagnosed, so any change in the intensity with which healthy, unhealthy, or dead old men are examined might produce an appreciable artifactual trend in recorded morbidity, perhaps of the order of several percent in the last decade.

Furthermore, 30 years ago about 20% of the people certified as dying of cancer in the State of Connecticut did so without generating either any medical record of cancer that was forwarded to the registry or even any such record that, knowing the patient to have died of *cancer, the registry could, subsequently trace. By the 1970's, the corresponding figure was only about 2%. To the extent to which this change was due to progressively more thorough coverage of medical records by the registry, a concomitant trend toward more complete registration of nonfatal cancers would be expected. This will produce artifactual increases in disease registration rates that may, for some types of cancer, amount in some periods to a few percent per decade.*

When, in 1979–80, we began our report, we intended to estimate the trends in U.S. cancer onset rates chiefly by means of morbidity data, because the site of origin and type of a cancer are likely to be recorded more reliably by a cancer registry than on a death certificate; moreover, trends in registration rates should not be biased by trends in the effects of cancer therapy. When we came to examine the available data, however, we were reluctantly forced to the conclusion that, for the common types of cancer, the U.S. trends since 1950 would be estimated more reliably from the mortality data (among Americans <65 yr) than from the morbidity data. This was not a conclusion that we welcomed because it prevented us from examining the separate trends for certain subtypes of cancer that are not separated in the published mortality data. The evidence that forced us to this conclusion was therefore presented at some length (pp. 1270–1281) in "Appendix C" of our report. For some of the less common types of cancer, such as Hodgkin's disease, childhood leukemia, and various embryonal neoplasms, of course, improvement in therapy dominate the trends in mortality. However, for the common cancers, no such large improvements in curative treatment occurred during the third quarter of the century. Despite this, however, some quite marked divergences still exist between the trends in recorded mortality and those in recorded morbidity (see text and text-figs. C4, C5, and C6 in our paper), and we eventually concluded that these divergences must be due chiefly to artifacts in the U.S. morbidity trends rather than in the U.S. mortality trends.

Our general preference for mortality data, however, relates to the assessment of recent trends only in the United States. It does not imply that we believe that U.S. cancer mortality data for other epidemiologic purposes, or that trends in registry data in other countries are necessarily less reliable than mortality data, either for the assessment of trends or for the purpose of comparing the absolute cancer onset rates in different countries. (Indeed, in many parts of the world where mortality data are poor, cancer registry data may be far more reliable, which is why we used them in section 3 of our report.) None of the points made by Drs. Clemmesen and Nielsen bear directly on the limited question of the relative merits of U.S. mortality data and U.S. morbidity data for the assessment of U.S. trends, and certainly none outweigh the many considerations listed in "Appendix C" to our original report.

Turning to their detailed points that do have some bearing on this main issue, 1) we do not regard the trends in morbidity data as preferable for bladder neoplasms; 2) the trends in U.S. breast cancer morbidity data are far from steady; they are grossly irregular, with a 15% increase over one 3-year period (1971–4) being followed by a 5–10% decrease over the next 3 years; 3) we noted in our text the beneficial effects of screening on cervical cancer (and the generally decreasing proportion of women with a cervix); and 4) precisely because of the increasing tendency for rectal cancer to be misdiagnosed as colon cancer (which we recognized and discussed), we examined only the trends in death certification for the aggregate of rectum, colon, large intestine (part unspecified), small intestine, and intestine (part unspecified).

Subject to the various sources of uncertainty noted in our original report, we still do not accept that there is at present any good evidence for a generalized increase in U.S. cancer onset rates over and above what could plausibly be ascribed to tobacco. Thus, although we hesitate to disagree with Dr. Clemmesen, who directly or indirectly has taught us so much about the value and limitations of the data from cancer registries worldwide,[3,4] we cannot see that his arguments require us to modify our main conclusions. It is, however, a pleasure to end by acknowledging the important contribution that continues to be made both by his own and by the Connecticut and New York cancer registries.

Immunity to Tumor-Associated Antigens in Vasectomized Men [1,2,3,4]

Deborah J. Anderson, [5,6] **Nancy J. Alexander,** [5,7] **David L. Fulgham,** [5] **Arthur A. Vandenbark,** [8] *and* **Denis R. Burger** [8,9]

ABSTRACT—Leukocytes from 49 vasectomized and 57 age-matched nonvasectomized men were tested in the leukocyte adherence inhibition (LAI) assay for reactivity to sperm and various 3-*M* KCl human tumor extracts. Forty-four percent of the vasectomized men and 15% of the control group were reactive to the sperm antigen preparation ($P \leq 0.03$). Similarly, a significantly higher percentage of vasectomized men responded to 3 of 5 tumor extracts tested: melanoma I (34.7 vs. 15.8%, $P \leq 0.04$), squamous cell carcinoma (48.8 vs. 26.0%, $P \leq 0.04$), and breast carcinoma (19.5 vs. 4%, $P \leq 0.04$). Thirty percent of vasectomized versus 4% of the control group responded to more than two tumor antigens ($P \leq 0.03$). The degree of LAI reactivity to each tumor extract was highly correlated with degree of antisperm LAI reactivity, and the degree of LAI responsiveness to one of the melanoma extracts was significantly correlated with antisperm antibody titer as measured by the sperm-immobilization assay. Furthermore, nonresponsive leukocytes from the control population converted to tumor antigen-responsive when incubated with sera from vasectomized LAI-positive men. Data from this study indicated that a large percentage of vasectomized men with sperm immunity were responsive to tumor-associated antigens in the LAI test and that antisperm antibodies or other serum factors played a role in this response. These results and the evidence that most tumor antigen-responsive cancer patients also have serum antibodies that reacted with sperm suggested that vasectomized men and cancer patients frequently responded to immunologically cross-reactive antigenic determinants present on both sperm and tumor cells.—JNCI 1982; 69:551–555.

Autoimmunity to spermatozoa often develops after vasectomy in experimental animals and men (*1*). Immunohistologic studies performed by us and others [for review, *see* (*1*)] have revealed that a variety of sperm antigens can elicit autoimmune responses and, furthermore, that considerable individual variation exists in the dynamics and specificity of vasectomy-induced antisperm responses (*1*, *2*). Since spermatozoa appear to express antigens similar in structure to surface markers found on early embryos (*3*) and malignant tissues (*4*) and since such differentiation antigens have been demonstrated to elicit immune responses in adult syngeneic animals (*5*), we designed the present study to determine whether vasectomized men with antisperm immunity demonstrate cross-reacting immunity to tumor-associated antigens.

MATERIALS AND METHODS

The LAI assay used in this study has been described in detail elsewhere (*6*). Soluble antigens were extracted from various human tumors (2 melanomas from different individuals, a pool of 7 squamous cell carcinomas of the head and neck, a single breast ductule carcinoma, and a single neuroblastoma) or from normal human breast (control) tissue with 3 *M* KCl according to the method of Meltzer and associates (*7*). Additionally, antigens were obtained from thrice-washed human ejaculated sperm by 0.4 m*M* 1,4-dithiothreitol treatment (sonication, 3×20 sec). Heparinized blood was drawn from 49 vasectomized and 57 age-matched nonvasectomized (control) men between the ages of 28 and 59 years. Leukocytes obtained by dextran sedimentation were incubated with several concentrations of each antigen or with medium alone (incubated control), were subsequently transferred to wettable plastic tubes, and then incubated for an additional 2 hours at 37°C so that adherence could occur. Nonadherent cells were enumerated in a Coulter counter, and LAI values were calculated by the formula: Percent inhibition = {[nonadherent cells (test sample − incubated control sample)]/(total cells − nonadherent incubated control cells)} × 100.

Plasma samples were analyzed for antisperm antibodies by: *a*) the macroscopic SA test in gelatin, *b*) the complement-dependent SI assay; and *c*) indirect immunofluorescence on methanol-fixed, intact or 1,4-dithiothreitol-treated sperm (*8*).

Arming of control (nonreactive) leukocytes with sera from LAI-reactive vasectomized men was performed according to the method of Thompson et al. (*9*) to determine if serum factors (such as antisperm antibodies) were mediators of LAI reactivity in these studies.

Data were subjected to frequency analysis by contingency table testing for independence and were corrected for continuity (Yates' correction). For this statistical test, vasectomy

group LAI values were considered positive for a certain antigen if they were greater than values obtained from 95% of the control population tested against the same antigen at the same concentration. (By this definition, ≈5% of the control population reacted to each antigen.) For this same analysis, we considered any titer (SA or IF) greater than or equal to 10 and SI values (percent sperm motile in control/percent motile in test) of greater than or equal to 5.0 to be positive. This analysis was termed the 95% cutoff method. A second method, the K-S two-sample test, was also used to determine the LAI cutoff value giving the maximum difference between percent responders in the control and vasectomy groups for each antigen tested (*10*). The data were also analyzed by Kendall's coefficient of rank correlation, a distribution-free statistical test, for correlation of degree of antisperm immunity (in humoral and LAI assays) to degree of antitumor reactivity and by two-sample ANOVA with the Mann-Whitney *U* test (*11*).

RESULTS

Antisperm Immunity

When the 95% cutoff method was used to determine significant reactivity levels, 77.6% of the vasectomized men and only 17.5% of the controls had detectable antisperm immunity in at least one of the assays ($P \le 0.001$). Of the vasectomized men, 68% had SA antibodies, 34.7% had SI antibodies, and by IF assay 12.2% had IgG and 20.8% had IgM antisperm antibodies. Antibodies to protamine, a sperm nuclear antigen, were found in 29.3% of the vasectomy group. Only 3.6 and 5.5% of the control group had detectable SA or SI antisperm antibody titers, respectively; 1.8% had IgG IF antibodies, 14.5% had IgM IF antibodies, and 9.5% had antiprotamine IF antibodies (SSH) (table 1).

When the K-S method was used for statistical evaluation, we found that 68.1% of the vasectomized men had SA antibodies, 69.4% had SI antibodies, 38.8% had IgG antibodies, 41.7% had IgM antibodies, and 29.3% had antiprotamine antibodies, compared to the controls with values of 30.9% for SI antibodies, 16.1% for IgG antibodies, 28.6% for IgM antibodies, and 9.5% for antiprotamine antibodies. By both statistical analyses the percentage of vasectomized men positive for SA, SI, and antiprotamine antisperm antibodies was significantly higher than that of the control group (table 1).

By the K-S method, 15 (44.1%) of 34 vasectomized men were significantly ($P \le 0.03$) reactive to sperm antigen in the LAI test, and of these 15 men 14 (93.3%) had antisperm antibodies as detected by SA or SI tests. Only 4 (14.8%) of 27 nonvasectomized controls were LAI-reactive to sperm antigen ($P \le 0.03$). Antisperm LAI reactivity significantly correlated with the presence of antisperm immobilizing antibodies ($P \le 0.05$) but did not correlate with any other types of antisperm antibodies.

Analysis of variance (Mann-Whitney *U* test) generally confirmed the other statistical analyses. Vasectomized men had significantly more SA ($P \le 0.001$), SI ($P \le 0.001$), IgG ($P \le 0.007$), and antiprotamine ($P \le 0.02$) antibodies but did not have significantly more immunity to sperm as measured by LAI (table 1).

We also tested sera from cancer patients with known LAI reactivity (*6*) in the IF assay for IgG antisperm antibodies. From 32 of these cancer patients, 24 (75%) had antisperm antibodies (table 2). Compared to the sera of the control group, significantly more cancer patient sera exhibited antibodies ($P \le 0.005$).

TABLE 2.—*Antisperm antibodies*[a] *in cancer patients with positive LAI reactivity to corresponding tumor extract*

Group	No. tested	No. with antisperm antibodies (%)
Control (nonvasectomized men)[b]	14	3 (21)

Neuroblastoma	6	5 (83)
Squamous cell carcinoma	16	12 (75)
Melanoma	10	7 (70)

[a] Indirect IF with fluorescein isothiocyanate–goat antihuman IgG.

[b] Nonvasectomized men who responded in the LAI assay to at least one or more antigens.

Antitumor Immunity

By K-S evaluation, significantly more vasectomized men than control men responded to squamous cell carcinoma (48.8 vs. 26.0%, $P \leq 0.04$), breast carcinoma (19.5 vs. 4%, $P \leq 0.04$), and melanoma I extract (34.7 vs. 15.8%, $P \leq 0.04$). In contrast, reactivity of vasectomized men to the normal breast antigen (control) was not significantly different from that of the control group at any protein concentration in the range of those tested for the tumor extracts. Results of all statistical evaluations are shown in table 3.

Of the total study group, 90% responding to breast carcinoma antigen, 88.9% responding to melanoma II, 85.7% responding to neuroblastoma, 80.8% responding to melanoma I, and 72.5% responding to squamous cell carcinoma in the LAI assay had antisperm immunity detectable in LAI or antibody assays. The percent of men with antisperm immunity was 45.3%; thus the frequency of antisperm immunity in all the tumor antigen-positive groups was significantly higher than expected by chance. By Kendall's statistical test, antisperm LAI reactivity was highly correlated with reactivity to each of the tumor extracts ($P \leq 0.001$). Various types of antisperm antibody titers were also significantly correlated with LAI reactivity to certain of the tumor antigens (table 4).

Of those 54 individuals tested against all five antigens, 48% of the vasectomized men versus 33% of the controls responded to at least one of the five tumor antigens tested. Thirty-seven percent of the vasectomized men versus 15% of the control group responded to at least two different tumor antigens, and 30% of the vasectomized but only 4% of the control group responded to three or more tumor antigens ($P \leq 0.03$). Fifteen percent of the vasectomized and none of the control group responded to all five antigens. All of the vasectomized men and half of the control men that responded to at least one tumor antigen (82%) had detectable antisperm immunity in either the LAI or antibody assays; 100% of the men in both groups responding to three or more tumor antigens had detectable antisperm immunity (text-fig. 1).

Arming Study

We used sera from tumor antigen-responsive vasectomized men with antisperm antibodies and sera from control men with no demonstrable antisperm antibodies in an arming study to determine if serum factors confer LAI responsiveness to nonresponsive (control) leukocytes. The data are presented in table 5. Significant arming was obtained when squamous cell carcinoma extract was used as the test antigen ($P \leq 0.01$) and when the data for all antigens were pooled ($P \leq 0.005$).

DISCUSSION

The LAI assay, originally described by Halliday and Miller (*12*), has proved to be a sensitive in vitro method for detection of specific immunity to a variety of antigens in both experimental animals and man (*13*). Several clinical research groups currently use the LAI assay to monitor specific reactivity to tumor-associated antigens in cancer patients (*6*), and this assay has also been used to detect antisperm immunity in animals and man (*14*). At least two separate mechanisms appear to underlie the LAI response: *a*) adherence inhibition mediated by a soluble lymphokine-like factor (LAI factor) released by sensitized lymphocytes upon contact with specific antigen (*15*) and *b*) nonadherence of monocytes and possibly other leukocytes induced by the binding of antigen to cytophilic antibody on the cell surface (*9*). Our ability to arm nonresponder leukocytes with sera from tumor-responsive vasectomized men suggests that one mechanism in our model is cytophilic antibody-dependent. Absorption–elution studies with serum arming factors could provide an approach for characterization of the antigens involved in this response.

The various forms and large amount of data assimilated in this study made thorough statistical analysis crucial. We used a number of specialized statistical analyses: The K-S cutoff method, which is nonparametric, was perhaps the most appropriate and in general agreed with the more standard tests for comparison of two populations (χ^2 analysis with 95% cut-off, analysis of variance). These tests revealed that vasectomized men had significantly higher antisperm antibody titers than did the controls in most antibody assays and that significantly more vasectomized men responded to the melanoma I, squamous cell carcinoma, and breast carcinoma extracts. The Kendall's rank order test is a powerful statistical tool that enabled us to make the statement that degree of reactivity to the melanoma extract was positively correlated with antisperm antibody level (SI test).

Embryonic antigens are known to be reexpressed on some malignant tissues, and several of these have been biochemically characterized (*16, 17*). Sperm express differentiation antigens that are found on early embryos (although these have not been well characterized), and sperm antigens can also be found on malignant tissues (*18*). The biologic function of these cell surface structures is not known. Vasectomized men did not respond to the control antigen (normal breast tissue) used in this study, but a larger panel of both normal and malignant tissues should be used in future tests to show more conclusively a tumor association and identify the types of tumors expressing these antigens.

Our preliminary observation that many cancer patients have high titers of antisperm antibodies is interesting in the context of this report because it further reports the hypothesis that sperm and malignant cells express immunologically cross-reactive antigens that readily stimulate a host autoimmune response. Serologic studies including absorption of antisperm reactivity in cancer sera with various types of tumor tissue should reveal the distribution of these antigens.

There is accumulating evidence that immunity to tumor-associated oncofetal antigens can affect the subsequent development of tumors (*19, 20*). However, although LAI reactivity to tumor extracts appears to arise from exposure to specific tumor antigens (i.e., in cancer patients) (*6*), the expected inverse correlation between LAI reactivity and tumor incidence or tumor growth rate has yet to be established. Nonetheless, from the data presented here, a tempting speculation is that the development of neoplastic disease in some vasectomized men with antisperm immunity could be affected by a cross-reacting immune sensitivity to tumor-associated antigens.

Unscheduled DNA Synthesis in Human Oral Mucosa Treated With Chemical Carcinogens in Short-Term Organ Culture[1,2]

Fumio Ide,[3,4] **Takatoshi Ishikawa,**[3,5] **Minoru Takagi,**[6] **Shinichiro Umemura,**[4] *and* **Shozo Takayama**[3,7]

ABSTRACT—Unscheduled DNA synthesis (UDS) was investigated by autoradiography in human oral mucosa treated with 10 representative chemical carcinogens. Small sections of gingiva in short-term organ culture were exposed for 2 hours to chemical carcinogens plus [*methyl*-^{3}H]thymidine. Significant numbers of silver grains, indicating UDS, were detected over the nuclei of both epithelial cells and fibroblasts. All ultimate or proximate carcinogens tested induced UDS. Of five procarcinogens tested, only benzo[*a*]pyrene (BP) did not induce UDS, but the more activated metabolite of BP, (±)-*trans*-7β-8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene (BPDE I), was very effective in inducing UDS. Ultimate or proximate carcinogens induced higher levels of UDS than did procarcinogens. All the carcinogens that induced UDS showed clear dose-dependent effects. UDS levels were twofold to fivefold higher in the epithelial cells than in the fibroblasts, regardless of the type of carcinogen tested. Comparisons of the levels of UDS induced by 4-(hydroxyamino)quinoline 1-oxide, methyl methanesulfonate, or BPDE I did not reveal any significant differences. These findings indicate that human gingival epithelial UDS assay should be useful for short-term detection of environmental carcinogens that induce cancer in human oral mucosa.—JNCI 1982; 69:557–563.

Because most chemical carcinogens in their ultimate reactive form are electrophils that react with DNA, they may induce DNA repair (*1*). Thus measurement of DNA repair could be a reliable method for determination of their carcinogenic potential (*2, 3*). Inasmuch as DNA damage and repair synthesis in various human tissues obviously cannot be measured by in vivo administration of chemicals, as has been done in experimental animals, an in vitro model must be developed that can be applied to human tissue. Several studies have shown that UDS in cultured human cells is a suitable marker for use in in vitro bioassay of carcinogens (*4–11*).

The oral cavity probably is the region of the body exposed to the highest levels of naturally occurring and synthetic chemical carcinogens present in the food and atmosphere, but no attempts have been made to assay UDS induced by carcinogens in oral tissues. We previously showed that UDS was induced in short-term organ culture of the oral tissues of adult rats and hamster embryos after application of two carcinogens (*12*). The organ culture system is more similar to the in vivo state than are cell culture systems, and it may eventually prove valuable for identification of possible carcinogens and of critical target populations of cells within a tissue.

This paper presents our findings on the abilities of 10 representative chemical carcinogens to induce UDS in human gingiva, on the differences between DNA repair in epithelial cells and fibroblasts, and on the individual differences in UDS in explants from several patients.

MATERIALS AND METHODS

Chemicals.—The following chemicals were purchased from the sources indicated: MMS, BP, DENA, and DMN from Tokyo Kasei Co., Tokyo, Japan; MNU, 4HAQO, and 4NQO from Iwai Chemical Co., Tokyo; MNNG from Wako Pure Chemical Co., Tokyo; mitomycin C from Kyowa Hakko Kogyo Co., Ltd., Tokyo; and [*methyl*-^{3}H]dThd (sp act, 60 Ci/mmol) from New England Nuclear Corp., Boston, Mass. The purities of these chemicals were as specified by the manufacturers. The following chemicals were gifts: N-OH-2-FAA from Dr. K. Umezawa, University of Tokyo, Tokyo; BPDE I and BPE from IIT Research Institute, Chicago, Ill., under the auspices of Dr. D. Longfellow, the National Cancer Institute, Bethesda, Md.

Induction of UDS in human oral mucosa.—Human gingivae were obtained from 20 gingivectomized patients at the Department of Periodontology, Faculty of Dentistry, Tokyo Medical and Dental University. Healthy portions of tissue were cut from the specimens. These specimens were brought within 2 hours to our laboratory in L-15 (Grand Island Biological Co., Grand Island, N. Y.) containing streptomycin (500 μg/ml) and penicillin (500 IU/ml) at 4°C. An

best copy available

outline of the procedure for organ culture was reported in (*12*); specific details were as follows:

All specimens were cut with a sharp razor into pieces of about 1 mm^3 under a dissecting microscope. Small pieces (5 or 6) were then incubated together for 2 hours at 37°C in an organ culture dish in 2 ml of L-15 containing [*methyl*-^{3}H]dThd (10 μCi/ml) and a carcinogen. Organ culture dishes were maintained in a chamber in an atmosphere of 50% N_2 and 50% O_2. Water-soluble carcinogens were dissolved directly in L-15 with stirring. Other carcinogens were dissolved in DMSO and then diluted with L-15 (highest final concentration of DMSO, 1%). All carcinogens were tested at three different doses. Carcinogen dose ranges were determined on the basis of previous reports (*6, 9, 12–14*). Each carcinogen was tested in tissue from a single patient, partly because of the scarcity of the material. Controls were included for all experiments; i.e., specimens were in either L-15 containing [*methyl*-^{3}H]dThd or in L-15 containing [*methyl*-^{3}H]dThd plus DMSO.

After incubation, the specimens were washed several times with cold L-15 and fixed with 10% neutral Formalin. All the specimens in a dish were embedded together in paraffin, with the same orientation relative to the surface of the epithelium as determined under a dissecting microscope. The usual histologic sections of 4- to 5-μm thickness were cut and then were treated with 3% perchloric acid for 45 minutes, with three changes of solution at 4°C for removal of the acid-soluble fraction. Sections were dip covered with NR-M_2 emulsion (Konishiroku Photo Co., Tokyo) and placed in the dark for 5 weeks at 4°C. Autoradiographs were developed, fixed, and then lightly stained with H & E.

Grain counting, under a 100× objective lens of a Nikon microscope, was done on 300–400 nuclei of randomly selected cells from the spinous layer of the epithelium of each explant (*12*). Counts were also made on subepithelial fibroblasts for comparison. Background numbers of grains were counted in the same way.

Estimation of the dThd pool.—The possibility of a difference between the dThd pools of epithelial cells and fibroblasts was studied by means of control autoradiographs. With autoradiographic procedures as described for the UDS study, but with a shorter exposure period (3 days), the numbers of silver grains on S-phase cells could readily be counted. Grains were counted on 50 epithelial cells and 50 fibroblasts. Because the numbers of S-phase cells were relatively few, grain counts were collectively made on tissues obtained from 5 individuals.

Comparisons of UDS.—Comparisons were made of UDS levels in tissues from 4 patients who had been simultaneously treated with the most effective UDS-inducing dose of 4HAQO or MMS. Similarly, tissues were examined from 3 other patients who had been exposed to BPDE I or BPE.

RESULTS

Induction of UDS in human oral mucosa.—Of the 10 carcinogens tested, 5 were ultimate or proximate carcinogens (MMS, MNU, MNNG, 4HAQO, and N-OH-2-FAA) and 5 were procarcinogens that require metabolic activation (BP, DENA, DMN, 4NQO, and mitomycin C). After treatment with each of the carcinogens (except BP), UDS could be clearly seen as silver grains on the nuclei of gingival epithelial cells and fibroblasts (figs. 1–3). The amount of UDS was greater near the edge than in the center of the specimens, probably because of the limited diffusion of [^{3}H]dThd and the carcinogen, as mentioned by Cleaver (*15*). However, the numbers of grains were constant in a zone of about 200 μm from the lateral edge of all explants. Thus we counted grains on the nuclei of randomly selected cells from the spinous layer within this zone, which contained approximately 1,000 cells. In the present study, UDS grains were clearly distinguished from grains of S-phase cells, inasmuch as S-phase cells were heavily labeled and were mainly located in the basal layer of the epithelium. Only background numbers of grains (0.2–0.4 grain/cell) were seen on the nuclei of control specimens (fig. 4). Mean values with standard deviations of the mean for the grain count on each explant are given in table 1.

All of the ultimate or proximate carcinogens tested induced UDS at various levels. Of the procarcinogens, DENA, DMN, 4NQO, and mitomycin C induced UDS, but BP did not.

As shown in table 1, the highest average grain number in carcinogen-treated groups was about 50 times that in the

[a] Values are means ± SD for each explant from 1 patient.

control group. All of the carcinogens that induce UDS showed clear dose-dependent effects. Ultimate or proximate carcinogens induced higher levels of UDS than procarcinogens. UDS levels were twofold to fivefold higher in the epithelial cells than in the fibroblasts, regardless of the type of carcinogen tested.

Estimation of the dThd pool. The mean grain numbers formed on S-phase nuclei of both epithelial cells and fibroblasts are given in table 2. No marked differences were observed in the average number of grains on the S-phase nuclei of epithelial cells and fibroblasts.

Comparisons of UDS.—Comparisons of UDS in human oral mucosae from 4 patients are shown in table 3. The amounts of UDS induced by 4HAQO or MMS were not significantly different in these tissues. Similar results were obtained with BPDE I (fig. 5). However, the K-region epoxide BPE gave a negative result within 2 hours (table 4).

DISCUSSION

Apparently, most human cancers have an environmental etiology (*16, 17*). Thus it is important to detect environmental carcinogens to which humans are exposed and to remove these carcinogens from the environment. The best evidence for the carcinogenic potential of a chemical obviously is cancer induction in experimental animals, but tests on animals are expensive and time consuming. The feasibility of detection of carcinogenic chemicals by the induction of UDS being measured in various cultured cells has been explored (*3*). Many bioassay methods have been developed in which human fibroblasts are used (*6*), but these methods provide only limited information inasmuch as most human cancer of clinical significance appears to originate in epithelial cells rather than in fibroblasts (*8, 10, 18*). The ideal cells for use in development of a practical and reliable in vitro UDS assay are those from a readily accessible, differentiated epithelium—cells that are able to metabolize a large variety of procarcinogens and that have high activity in excision repair pathways (*8*).

Several studies on in vitro cultivation of human oral keratinocytes have been reported (*19–22*). However, so far as we know, no reports have appeared with regard to UDS assay of these cells. Recently, Lake et al. (*8*) demonstrated, by scintillation counting, the chemical induction of UDS in human foreskin epithelial cell cultures. These investigators mentioned that they first attempted to use autoradiography for detection of UDS in organotypic primary skin cultures, but because the epidermal keratinocytes are multilayered and are at various stages of differentiation, Lake and his colleagues observed significant variation in grain counts due to self absorption of [^{3}H]dThd. The results obtained in our studies indicate that autoradiography permits quantitative analysis of UDS in both epithelial cells and fibroblasts in architecturally and functionally intact human gingival tissue in organ culture.

As indicated under "Results," DENA and DMN induced UDS. These nitrosamines are present in the atmosphere of certain urban areas (*23*), in tobacco smoke (*24*), and in food (*25*), and may be formed in vivo by the reaction of secondary and tertiary amines with nitrites under acidic conditions (*26*). Although direct evidence is lacking, these findings suggest that these nitrosamines may induce cancer in human oral mucosa. However, BP, one of several important carcinogenic hydrocarbons found in the environment (*27*), did not induce UDS. The metabolism of BP by human skin epithelial cells has been studied in detail in organ culture (*28, 29*) and in cell culture (*30–32*). We believe that these observations indicate that BP may require a long time for metabolic activation and may not bind covalently to DNA within 2 hours, inasmuch as the more activated metabolite of BP, BPDE I, induced UDS in our present study.

Mitomycin C, which is widely used as a cancer chemotherapeutic agent, induced UDS in our system. This chemical was shown to induce interstrand cross-links in DNA, and these DNA–DNA cross-links may be repaired by both base and nucleotide excision repair pathways (*33*).

In the absence of direct information on biochemical measurement of DNA adducts, our autoradiographic method for studying DNA repair is speculative. Nevertheless, the results obtained in our studies provided evidence that epithelial cells are more proficient in DNA excision repair, as measured by UDS, than are fibroblasts, regardless of the type of carcinogen tested. The dThd pool, estimated from the intensities of S-phase cells, revealed little difference in epithelial cells and fibroblasts. Thus, we believe that the

UDS value would reflect DNA repair efficiency. Recently, Taichman and Setlow (*34*) reported that the extent of UV light-induced repair was similar in cultured human epidermal cells and dermal fibroblasts. Whether this difference reflects differences in experimental approach or in types of DNA damaging agents is not yet clear. Remember, however, that several studies have shown that the metabolism of carcinogenic hydrocarbons is higher in human skin epithelial cells than in fibroblasts (*8, 29, 30, 35*).

Much evidence exists for a prophylactic role of DNA excision repair in chemical carcinogenesis (*36, 37*). Other factors, such as the percentage of cells undergoing the cell cycle and the chance of exposure to carcinogens, may contribute to carcinogenesis (*38, 39*). The apparent lack of cell division in fibroblasts in vivo could render them less susceptible than dividing epithelial cells to the carcinogenic effects of chemicals, even if equal amounts of carcinogen are bound to the cell's DNA (*31*). These findings suggest that the role of excision repair in rapidly renewed epithelial cells is important in preventing carcinogenic initiation. Note that carcinogen-induced DNA damage, if not repaired before cell proliferation, is intimately related to the initiation-fixation process of carcinogenesis (*40, 41*).

The use of human tissues should be helpful in providing a link between studies on experimental animal and human cancers, for assessment of the validity of extrapolating carcinogenicity data on experimental animals to human beings.

Distribution of Hepatitis B Surface and Core Antigens in Human Liver Cell Carcinoma and Surrounding Nontumorous Liver[1, 2]

Setsuo Hirohashi,[3] **Yukio Shimosato,**[3] **Yoshinori Ino,**[3] *and* **Kiyozo Kishi**[3, 4]

ABSTRACT—The distribution of hepatitis B surface antigen (HBsAg) and core antigen (HBcAg) in surgically removed liver cell carcinomas of 60 Japanese patients was studied by an immunohistochemical method. HBsAg was localized in the cytoplasm, and HBcAg was mainly in the nuclei of normal-appearing liver cells, dysplastic liver cells, and tumor cells. In some instances both HBsAg and HBcAg were contained in the tumor cells and liver cells. HBsAg was found in the nontumorous liver tissue of 30 patients (50%); nine of the HBsAg-containing nontumorous livers also contained HBcAg. HBsAg and/or HBcAg was detected in tumor cells in 7 (23%) of 30 cases with HBsAg-positive liver diseases.—JNCI 1982; 69:565–568.

It is well known that liver cell carcinoma and cirrhosis are frequently associated with each other; HBsAg frequently occurs in sera of patients with liver cell carcinoma and in populations whose incidence of liver cell carcinoma is high. These phenomena suggest that both infection with HBV and cirrhosis play important roles in the development of liver cell carcinomas.

The presence of HBsAg in cells of liver cell carcinomas has been demonstrated with the use of immunohistochemical methods (*1–7*), whereas the presence of HBcAg in tumor cells remains questionable (*1, 2, 4, 5*).

In Japan, the incidence of liver cell carcinoma is relatively high, and surgical treatment of this carcinoma has been successful in some cases. With the use of surgically resected livers and a sensitive immunohistochemical method, we studied the distribution of HBsAg and HBcAg in liver cell carcinomas and in surrounding nontumorous livers. We also studied the relationship between HBV infection and the histology of nontumorous regions of livers in which neoplastic transformation had developed. The intent of this study was to clarify whether not only HBsAg but also HBcAg could be produced by liver cell carcinomas and to evaluate the roles of HBV and cirrhosis in human liver cell carcinogenesis.

MATERIALS AND METHODS

Cases.—Sixty primary liver cell carcinomas of Japanese patients were studied. They had been surgically resected at the National Cancer Center Hospital during the last 10 years. Hepatoblastomas and pure bile duct carcinomas were excluded from this study. Serum HBsAg of patients was measured by the reversed passive hemagglutination test (AUSCELL; Abbott Laboratories, North Chicago, Ill.), and anti-HBsAg was measured by the passive hemagglutination test (PHA Test Eisai Kit; Eisai Co., Ltd., Tokyo, Japan).

Immunohistochemical staining of HBsAg and HBcAg.—The unlabeled antibody PAP method of Sternberger (*8*) was used to demonstrate HBsAg and HBcAg on Formalin-fixed, paraffin-embedded sections. One section each of tumor tissue and nontumorous liver was initially selected at random and studied for each case, and in cases in which either or both of two antigens were positive in nontumorous liver, 4 more sections of tumor tissue were examined. Each section was about 2×3 cm in size. We used anti-HBsAg rabbit serum (Medical and Biological Laboratories Ltd., Nagoya, Japan), anti-HBcAg rabbit serum (*9*), swine immunoglobulins to rabbit immunoglobulins (DAKO-Immunoglobulins Ltd., Copenhagen, Denmark), and PAP complex (DAKO Immunoglobulins). These antisera were diluted with 0.01 *M* phosphate buffer (pH 7.2) with 0.8% NaCl (PBS) containing 10% normal swine serum to block nonspecific binding. Sections were deparaffinized in xylene, cleared in ethanol, and then incubated for 30 minutes in methanol that contained 0.3% hydrogen peroxide to remove the endogenous peroxidase activity. After being washed in PBS, the rabbit antiserum to HBsAg or HBcAg (diluted 1:100) was applied and incubated for 30 minutes at room temperature and then washed and incubated with swine immunoglobulins to rabbit immunoglobulins (diluted 1:20). After being washed, the sections were incubated with PAP complex (diluted 1:50), washed again, and developed for 5–10 minutes in 0.05 *M* Tris buffer (pH 7.6), that contained 0.02% DAB and 0.005% hydrogen peroxide. Subsequently, the sections were counterstained with Mayer's hematoxylin.

The specificity of the immunohistochemical staining was confirmed by the following controls: 1) replacement of the primary antiserum by the normal rabbit serum and 2) absorption of the primary antisera with excess amount of purified HBsAg and HBcAg. HBsAg was purified by affinity

[4] We are indebted to Dr. Shinobu Matsuda (Central Research Division, Takeda Chemical Industries, Osaka, Japan) for the gift of anti-HBcAg rabbit serum and to Dr. Masayasu Inoue (Kanagawa Prefecture Public Health Laboratory, Yokohama, Japan) for the gift of purified HBsAg and HBcAg. Surgical materials were provided by Dr. Hiroshi Hasegawa (National Cancer Center Hospital, Tokyo), photomicrographs were prepared by Mr. Etsuji Nishizaki (National Cancer Center, Tokyo), and the manuscript was reviewed by Mr. J. Patrick Barron (St. Marianna University School of Medicine, Kawasaki, Japan).

chromatography and HBcAg by zonal ultracentrifugation with metrizamide discontinuous gradient.

Double immunohistochemical staining.—To observe HBsAg and HBcAg simultaneously in the tissue, we studied all the sections with both antigens by the method described by Sternberger (*8*). The reactions were initially stained for HBcAg with the use of DAB as substrate. Then the antibodies bound were removed by elution in 0.1 *M* glycine-HCl buffer (pH 2.2) for 1 hour. After being washed in PBS, the sections were stained for HBsAg and developed for 20–30 minutes in Tris buffer that contained 0.02% 4-chloro-1-naphthol and 0.005% hydrogen peroxide at 37°C.

RESULTS

Cases and histology.—Of the 60 patients, 49 were male and 11 were female. The patients' ages ranged from 16 to 77 years with an average age of 52.1 years. The nontumorous livers were classified according to the recommendations by the World Health Organization (*10*) (table 1). Accumulation of dysplastic liver cells in nontumorous livers, named "liver cell dysplasia" by Anthony et al. (*11*), was found in 32 cases (53%), 22 of which showed the histologic characteristics of macronodular cirrhosis. Liver cell dysplasia was marked in 17 cases and was slight in 15 cases (table 2). The 60 tumors were histologically divided into 56 pure liver cell carcinomas and 4 combined liver cell and bile duct carcinomas, and the predominant area of the tumors was classified by the grading system of differentiation (table 3) introduced by Edmondson and Steiner (*12*).

Specificity of immunohistochemical staining.—Immunohistochemical staining of HBsAg and HBcAg resulted in brown reaction products with DAB and in pale-blue reaction products with 4-chloro-1-naphthol. Nonspecific background staining was virtually absent. Absorption of antisera against HBsAg and HBcAg by the respective antigens resulted in unstained sections. No reactions were obtained when the primary antisera were replaced by normal rabbit serum.

HBsAg and HBcAg in nontumorous livers.—Table 1 shows the results of immunohistochemical detection of HBsAg and HBcAg in relation to the histology of nontumorous livers, and table 4 compares the results obtained with serum HBsAg and anti-HBsAg.

The number of HBsAg-positive cells in nontumorous livers varied from case to case. HBsAg was localized diffusely in the cytoplasm or localized as cytoplasmic inclusion bodies (fig. 1).

TABLE 1.—*Hepatitis B antigens in nontumorous livers*

Histology of nontumorous liver	No. of cases (% of total)	HBsAg-positive and HBcAg-positive	HBsAg-positive and HBcAg-negative	HBsAg-negative and HBcAg-positive	HBsAg-negative and HBcAg-negative

[a] Results of immunohistochemical determinations.
[b] Assayed by reversed passive hemagglutination test.
[c] Assayed by passive hemagglutination test.

HBcAg was localized mainly in the nuclei of liver cells (fig. 1), but occasionally small amounts were also localized in the cytoplasm of liver cells. HBcAg-positive cells were often distributed in clusters, and their number varied from case to case. HBsAg was detected in all cases in which HBcAg was detected (table 1), and HBsAg-positive cells were more frequent than HBcAg-positive cells in most cases. HBsAg and HBcAg usually occurred in different cells, but a few scattered cells were observed to contain both HBsAg and HBcAg (fig. 1).

Table 2 shows the incidence of liver cell dysplasia in relation to the presence of HBsAg and/or HBcAg in nontumorous livers. HBsAg was localized in some of the dysplastic liver cells (fig. 2), but HBcAg was seldom seen.

HBsAg and HBcAg in tumors.—HBsAg and/or HBcAg was detected in various numbers of tumor cells in 7 cases (table 3), although tumor cells were predominantly negative for both antigens. In 2 cases, in which both HBsAg and HBcAg were detected, HBsAg-positive tumor cells were more frequent than HBcAg-positive tumor cells; tumor cells that contained both HBsAg and HBcAg were present in only one case; even in that case such cells were rare (fig. 3). In tumor cells, HBsAg was localized in the cytoplasm only, whereas HBcAg was mainly localized in the nuclei (fig. 3).

DISCUSSION

In autopsy studies, cirrhosis is recognized in more than 80% of patients with liver cell carcinoma in Japan (*13*). However, cirrhosis was present in only 61.7% of the cases in the present study of surgically resected livers. This is probably due to the fact that the cases in this series were operable. Cases without cirrhosis showed histologic findings of chronic active hepatitis, chronic persistent hepatitis, or almost normal liver. It is now clear that fully developed cirrhosis is not a prerequisite for the development of liver cell carcinoma (*13, 14*). However, cirrhosis is suspected of being able to play an important role in carcinoma development. The histologic type of cirrhosis (the so-called "posthepatitic cirrhosis") associated with liver cell carcinoma is predominantly macronodular: In this cirrhosis liver cell regeneration is prominent. Conversely, micronodular cirrhosis, in which liver cell regeneration is not so prominent, is rarely associated with liver cell carcinoma. Since liver cell regeneration increases susceptibility to carcinogens in animal experiments (*15, 16*), macronodular cirrhosis might be expected to play a similar role in human liver cell carcinogenesis.

HBsAg and HBcAg were clearly demonstrated in Formalin-fixed, paraffin-embedded sections of surgically resected livers by Sternberger's PAP method, the specificity of which was confirmed by adequate controls. In addition, the high sensitivity of the method was shown by the fact that the results of HBsAg localization in nontumorous livers completely coincided with the results of serum HBsAg measured by reversed passive hemagglutination test.

We observed a close relationship between liver cell carcinoma and HBV infection. HBsAg was detected in 30 cases (50%), and anti-HBsAg was detected in 11 cases (18%); therefore 68% of our series were cases with active HBV infection or a history of HBV infection.

Tumor tissues containing HBsAg and/or HBcAg were observed in 7 cases. In addition, a few tumor cells simultaneously contained both HBsAg and HBcAg. The results suggest production of complete virus by tumor cells and the presence of complete virus genomes in tumor cells. Recently, a cultured human liver cell carcinoma (PLC/PRF/5) was shown by molecular hybridization technique to possess complete genomes of HBV as an integrated form in host DNA (*17-20*). These findings are consistent with those seen in several oncogenic viruses in animals and indicate that HBV probably plays a major role in liver cell carcinogenesis.

If the HBV genomes were integrated in host DNA, all the tumor cells would contain the virus genomes. However, one tumor was composed of cells that contained either HBsAg or HBcAg, or both HBsAg and HBcAg, or neither HBsAg nor HBcAg. From this finding, it is speculated that HBV genes coding for HBsAg and HBcAg would be expressed under different and independent regulation at least in tumor cells.

Anthony et al. (*11*) and Anthony (*21*) reported that liver cell dysplasia was a precancerous lesion and was related to HBV infection. We do not know if dysplastic liver cells progress to cancer or not, but a close relation between liver cell dysplasia and HBV infection was observed in this study. In addition, the presence of HBsAg in some dysplastic liver cells may suggest the presence of integrated HBV genomes in dysplastic liver cells.

Our review of 60 resected cases shows that both HBsAg and HBcAg can be produced by liver cell carcinomas, and it further suggests important roles played by HBV and cirrhosis in the development of liver cell carcinoma.

Elevated dTTPase Activities in Sera of Patients With Advanced Cancer[1,2,3]

Nicolaus Dahlmann, *M.D.* [4,5]

ABSTRACT—dTTPase activities were determined in the sera of 108 healthy blood donors, 43 nonseriously ill patients, 66 seriously ill patients, 95 patients with untreated malignant diseases, 41 patients with breast carcinoma, and 53 umbilical cord blood samples. Values of 300 mU/liter or higher were taken as abnormal activity. Whereas the dTTPase activities of the nonseriously ill patients and the breast carcinoma patients were not significantly elevated, the dTTPase activities of 52% of the seriously ill patients and 82% of the patients with untreated malignant diseases were lying above the two standard deviation range.—JNCI 1982; 69:569–572.

Previously, we described a novel enzyme activity present in human serum (*1*). This enzyme, dTTPase, catalyzes the conversion of dTTP to dTDP. No measurable hydrolysis of nucleoside triphosphate to the diphosphate was observed with any of the other three standard deoxyribonucleoside triphosphates.

The unique characteristics of this enzyme suggest that it might be involved in the regulation of the rate of dTTP synthesis and thus may play an important role in the control of DNA synthesis (*2*). To date, positive correlations between growth rate of mammalian tumors and the levels of activity of key enzymes of pyrimidine synthesis in these tissues have been reported (*3*). The enzymes studied include dCMP deaminase (dCMP aminohydrolase, EC 3.5.4.12), thymidylate synthetase (N^5,N^{10}-methylenetetrahydrofolate: 2′-deoxyuridylate *C*-methyltransferase, EC 2.1.1.45), and dTMP kinase (ATP deoxythymidinemonophosphate phosphotransferase, EC 2.7.4.9) (*4*). Therefore, the idea was to see if the dTTPase activity was elevated in sera of cancer patients. Indeed, preliminary studies revealed increased levels of dTTPase activity in 19 sera obtained from patients with various untreated cancers as compared to the levels of dTTPase activity in sera obtained from healthy blood donors (*5*).

In the present paper, serum dTTPase levels are compared in *a*) healthy blood donors, *b*) nonseriously ill patients, *c*) seriously ill patients, *d*) patients with untreated malignant diseases, *e*) breast cancer patients, and *f*) umbilical cord blood samples. The objectives of this investigation were to determine *a*) whether elevated levels of dTTPase activity in the serum may serve as a marker for diagnosis of tumors, *b*) whether there is a specificity for different tumors, and *c*) whether there is any indication that the dTTPase is involved in a neoplastic process.

MATERIALS AND METHODS

Substrates.—Tetrasodium dTTP was obtained from Boehringer-Mannheim, Mannheim, Federal Republic of Germany. The ammonium salt of [methyl-^{3}H]dTTP was purchased from The Radiochemical Centre, Amersham, England, and diluted with unlabeled nucleotide solution to a concentration of 7–8 μCi/nmol.

Other chemicals.—Disodium dTMP and trisodium dTDP were obtained from Boehringer-Mannheim. Dithiothreitol was purchased from Sigma Chemical Co., München, Federal Republic of Germany. Polygram CEL 300 PEI precoated sheets were supplied by Macherey-Nagel Co., Düren, Federal Republic of Germany. Other standard reagents, all of analytical grade, were purchased from E. Merck A.G., Darmstadt, Federal Republic of Germany.

dTTPase assay.—The assay was based on the conversion of [^{3}H]dTTP to [^{3}H]dTDP and was performed under optimized conditions for each component. Each assay mixture contained, in a final volume of 50 μl, 10 m*M* Tris-HCl (pH 7.8), 0.5 m*M* MnCl$_2$, 8 m*M* dithiothreitol, 6 μ*M* [^{3}H]dTTP (7–8 μCi/nmol), and 5 μl serum. Both the reaction mixture and the serum were pipetted with a Hamilton digital diluter (Hamilton Bonaduz A.G., Bonaduz, Switzerland). Incubation was at 30°C for 1 hour, and the reaction was terminated by the addition of 5 μl of 50% formic acid (vol/vol) containing unlabeled dTTP, dTDP, and dTMP, all at 5 m*M*.

The reaction mixtures were immediately centrifuged (2 min, 10,000×*g*), and 5-μl aliquots of 20 supernatants were simultaneously applied to the PEI cellulose sheets with the Desaga autospotter (DesagA GmbH., Heidelberg, Federal Republic of Germany). The chromatograms were developed at room temperature with 1 *M* acetic acid containing 0.85 *M* LiCl, were dried, and were examined with UV light. The dTTP, dTDP, and dTMP spots were cut out, and radioactivity in each spot was determined by liquid scintillation spectrometry.

The enzyme activity was calculated from the amount of the hydrolyzed product formed. One international unit represented the production of 1 μmol dTDP/minute. The reaction rates were linear with time and enzyme concentrations up to 350 mU/liter under the conditions used.

Serum samples.—Blood was collected from patients and allowed to clot in the absence of any additives. The serum was separated by centrifugation and was stored at −20°C until assayed. The enzyme activity was stable to three cycles of freezing and thawing.

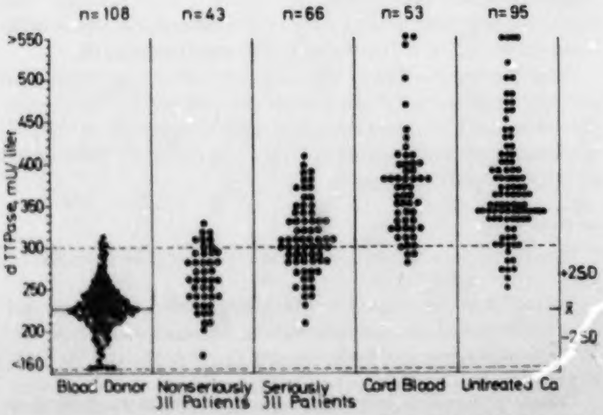
Sera of healthy blood donors were obtained from Dr. M. Moskophides, Chirurgische Universitätsklinik, Hamburg, Federal Republic of Germany, and from Professor Dr. K. Hoppe, Allgemeines Krankenhaus Eilbek, Hamburg. Various members of the staff of the Medizinische Universitätsklinik Hamburg provided patients' sera. Dr. F. Bode and Dr. G. Steinmann provided sera from both seriously and nonseriously ill patients, Professor Dr. R. Klapdor provided sera from patients with pancreatic and biliary tract carcinomas, and Dr. R. Pompecki provided sera from patients with gastrointestinal carcinomas. Sera from patients with laryngeal-pharyngeal carcinomas were obtained from Dr. R. Skoblo, Universitätsklinikum Steglitz, Berlin, Federal Republic of Germany, and sera from patients with hematologic tumors were obtained from Professor Dr. H. Stein, Pathologisches Institut der Universität, Kiel, Federal Republic of Germany. Professor G. Trams provided sera from breast carcinoma patients; the histologic examinations of the various samples were performed by Professor H. E. Stegner. Umbilical cord blood samples were obtained by Dr. H. Jagella, Krankenhaus Elim, Hamburg. All sera from the patients with untreated malignant diseases, as obtained from the persons mentioned above, suffered from carcinomas of stage 3.

RESULTS

Blood donors.—The dTTPase activity in the sera of the healthy blood donors ($n=108$) is demonstrated in text-figure 1. For normal blood donors the dTTPase level did not vary. Thus the data for the 67 males and 41 females were taken together, and a Gaussian distribution was seen. The average dTTPase value of 229 mU/liter and two standard deviations (SD=34 mU/liter) for the normal control are indicated on the scattergram. This cutoff limit was chosen so that about 95% of a healthy population had values below the limit.

Nonseriously ill patients.—Analysis of patients with diseases other than neoplasia showed a biphasic distribution in dTTPase activity. We divided the population into 2 groups, which we called nonseriously ill patients and seriously ill patients (characterized by severe destruction of tissues and serious inflammations) according to the diseases that are summarized in the tables for these 2 groups. Diseases of the nonseriously ill patients are listed in table 1. Although the numbers of the cases in the various disease categories were not high enough to be statistically significant for each disease, the reactions of the nonseriously ill patients were clearly similar to the reactions of the blood donors. The following values were obtained: $\bar{x}=263$ mU/liter and SD = 37 mU/liter. Only 16% were found to lie above the two standard deviations of the normal mean.



TEXT-FIGURE 1.—dTTPase activities expressed in mU/liter for healthy blood donors, nonseriously ill patients, seriously ill patients, umbilical cord blood samples, and patients with untreated malignant carcinoma (Ca).

TABLE 1.—*dTTPase activity: Nonseriously ill patients*

Disease	Patients			Enzyme activity, mU/liter		
	Total No.	No. positive[a]	Percent	Mean	SD	Range
Diabetes without organic complications	4	1	25	265	48	200–310

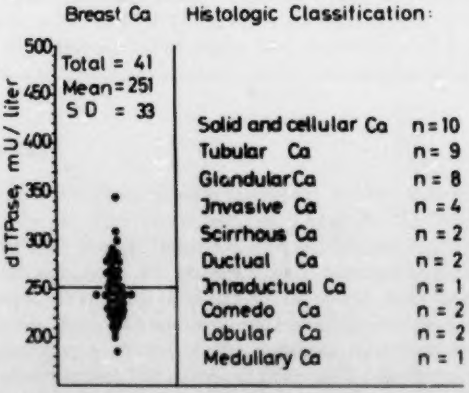
Biliary tract	5	5	100	352	26	320–390
Ovarian	6	4	67	358	86	280–520
Laryngeal–pharyngeal	6	6	100	372	18	350–390
Total	95	82	86	375	76	250–650

[a] Positives are all patients whose enzyme activity values are above the two standard deviation range of the normal mean (≥300 mU/liter).

specific diseases studied were 3/4 for diabetes with organic complications, 6/9 for cardiac infarction, 11/28 for inflammations, 4/6 for terminal renal insufficiency, and 1/3 for thrombosis. These results show that the sera of some patients with serious diseases other than cancer may have elevated dTTPase activities and that such increases are not restricted to cancer.

Malignant diseases.—All patients of this group as given in table 3 had a progessive malignant disease (stage 3) and were untreated. The mean and standard deviation for these probands were $\bar{x}$=375 and SD=76 mU/liter. Of 95 patients, 86% lay above the two standard deviation range. Positive values of 100% or nearly 100% were seen for patients with polycythemia vera, chronic lymphatic leukemia, rectal carcinoma, and laryngeal–pharyngeal carcinoma. The other diseases and the number of patients with dTTPase activities in the pathologic range per the total number of patients with specific diseases studied were 3/5 for malignant lymphoma, 12/14 for colon–sigmoid carcinoma, 11/14 for pancreatic carcinoma, and 4/6 for ovarian carcinoma.



TEXT-FIGURE 2.—dTTPase activities expressed in mU/liter for breast carcinoma (Ca) of different histologic groups.

Patients with breast carcinoma.—In contrast to the sera from patients with other monitored malignant diseases, sera from breast carcinoma patients revealed an average dTTPase activity of 251 mU/liter (SD=33 mU/liter) with a distribution quite similar to the distribution of the blood donors (text-fig. 2). Because of the relatively large group of 41 breast carcinomas analyzed and their different histologic classifications, it is quite probable that patients with breast carcinoma do not have an elevated dTTPase activity. The reason for this result is not known, and further investigations of the biochemical and clinical aspects of breast carcinoma must be done to clarify this observation.

Umbilical cord blood samples.—Values for sera from umbilical cord bloods are shown in text-figure 1. The distribution of the data resembled the distribution for untreated malignant diseases inasmuch as about 90% of the 53 values lay above the two standard deviation level. The dTTPase activity in cord blood ranged from 280 to greater than 550 mU/liter.

DISCUSSION

This report describes elevated serum dTTPase activities in association with some nonmalignant diseases and with various untreated malignant diseases. The nonmalignant diseases could be divided into 2 groups, inasmuch as the nonseriously ill patients had serum dTTPase activities like those of healthy blood donors. However, 52% of the seriously ill patients had serum dTTPase activities above the two standard deviation range of values found for sera from healthy blood donors. In terms of a potential tumor marker, these results are by no means satisfactory because of the apparent lack of specificity for malignant disease. One must also consider that elevated serum dTTPase activities are restricted to patients with specific disease entities that are characterized by severe destruction of tissue. Under circumstances of a differential diagnosis, the determination of dTTPase activity in human sera might be a useful tool for monitoring the presence of cancer, inasmuch as the true positive rate for untreated human malignant diseases is greater than 80%. The only exception known so far is breast carcinoma, and this finding is not well understood because we have insufficient knowledge regarding the function and origin of dTTPase activity in human sera.

The test system as described above is simple, inexpensive, and accurate; it is not time consuming and could be used as a mass screening test for cancer. Other diseases such as cardiac infarction or apoplexy that result in increased levels of dTTPase activity in the serum could be easily diagnosed.

Furthermore, we speculate that the dTTPase assay can be made more specific because about 25% of the sera from patients with untreated carcinomas have values above the two standard deviation range of 400 mU/liter of the seriously ill patients, indicating that in serum in general at least two enzymes are acting on the dTTP substrate, one enzyme being an unspecific degrading enzyme and the other being specific and involved in the proliferation process. This suggestion is supported by the fact that the samples of the umbilical cord blood used as a model for a proliferating tissue show a distribution of dTTPase activity that is absolutely similar to the pattern exhibited by sera from untreated carcinomas.

The elevation of the dTTPase activity in cord blood is interesting to note because in another paper a DNA-binding protein was described that was elevated in the sera of patients with various untreated malignant diseases but was not elevated in umbilical cord blood samples (*6*). Another hint for the existence of more than one enzyme acting on dTTP as a substrate was the attempted determination of the K_m (Michaelis constant) value from a reciprocal plot, which led to a downward-bent hyperbolic curve typical for the hydrolysis of one substrate by two enzymes (Dahlmann N: Unpublished observations). So the future task is to see if really two or more enzymes are hydrolyzing the dTTP and if there might be one which is specifically regulating the proliferation process as formerly discussed (*1*).

Breath Methane Excretion in Patients With Unresected Colorectal Cancer[1,2]

David A. Karlin, *M.D.,*[3] **R. D. Jones,** *M.S.,*[3] **John R. Stroehlein,** *M.D.,*[3] **Anthony J. Mastromarino,** *Ph.D.,*[3] *and* **Gregory D. Potter,** *M.D.*[3]

ABSTRACT—The objective of our study was to verify or refute the observation that patients with unresected colorectal cancer are more likely to be breath methane excretors than the general population. Intracolonic heme had no effect on breath methane excretion of 11 normal volunteers given oral hemoglobin. Laxative–enema colonoscopy preparation had a profound effect on the subsequent measurement of breath methane. Three of 4 volunteer methane excretors became nonexcretors, and 2 remained nonexcretors for 21 days and 7 months, respectively. No significant difference was found in the frequency and the amount of breath methane excretion in 55 patients with unresected colorectal cancer and in 99 control subjects. However, 13 patients with unresected descending or sigmoid colon cancers were almost twice as likely to be breath methane excretors as 38 patients with colorectal cancer at other sites.—JNCI 1982; 69:573–576.

Large bowel cancer is a leading cause of morbidity and mortality in the United States (*1*). Because the etiology is unknown, current research concerns the detection of premalignant conditions, the screening of large populations by proctosigmoidoscopy, and tests for fecal occult blood (*2, 3*). To enhance the cost-effectiveness of screening, simpler or more effective tests are needed for screening large populations for selection of subgroups that are at increased risk for developing large bowel cancer.

Although it has been suggested that the colonic microflora plays a role in the etiology of colorectal cancer, significant differences in the flora composition have been difficult to demonstrate. However, significant differences in metabolic activities of the flora have been reported (*4–7*). Because breath methane excretion is an indirect measurement of the metabolism of the anaerobic colonic flora, the breath methane content in patients with carcinoma of the large bowel has been studied. In a prospective study, Haines et al. (*8*) found that 80% of 30 patients with unresected large bowel cancer excreted more than 1 ppm methane in their breath compared with 40% of 272 control subjects. Here we report results of a retrospective study and the effects of heme or laxative and enema treatment on breath methane concentrations.

METHODS

Subjects.—This study was approved by the Surveillance Committee at The University of Texas M. D. Anderson Hospital and Tumor Institute, and study participants gave informed consent. All patients had roentgenographic or endoscopic diagnosis of a colon or rectal neoplasm and subsequent biopsy or resection for histologic confirmation of adenocarcinoma. None of the patients had symptoms of bowel obstruction. Fifty-five patients with colorectal cancer were studied before surgical resection. Prestudy data included age, sex, race, anatomic location of large bowel cancer, history of previous intestinal surgery, colorectal polyps and use of antibacterial medication, chemotherapy, laxatives, enemas, and antibowel motility drugs during the preceding month. Ninety-nine control subjects were comprised of patients' spouses and normal volunteers.

Collection, storage, and transport of breath samples.—We collected duplicate end-expiratory breath samples from all subjects by using an apparatus consisting of a 2-liter rubber anesthesia bag connected to a one-way valve with an air sample tap and on-off valve and a female connector on the bag side of the one-way valve. The mouth side of the one-way valve was connected to a mouthpiece with a segment of flexible tubing. The first of three end-expiratory breath samples was discarded for reduction of dead-space error.

To validate our method for storage and transport of breath samples, we collected end-expiratory breath samples from 2 subjects known to be breath methane excretors. With use of a gas-tight syringe, 20 50-ml aliquots from each subject were transferred to 20-cm^3 plain Venoject nonsiliconized rubber-stoppered evacuated tubes. Ten tubes each of 5 and 43.5 ppm methane in nitrogen standard, ambient air, and nitrogen were stored under identical conditions at room temperature up to 4 weeks. Five-milliliter samples were withdrawn at base-line and weekly intervals from unknown, standard, ambient air, and nitrogen tubes for gas chromatographic analysis. Up to four samples could be withdrawn from each tube.

Effect of laxative–enema preparation.—Because most of the subjects with large bowel cancer had radiographic or endoscopic confirmation of their diagnosis prior to referral, it was necessary to determine the length of time for the recovery of breath methane excretion in known excretors following laxative–enema colonoscopy preparation. Daily end-expiratory breath methane concentrations were determined on 4 healthy volunteers (table 1). On day −2 a full liquid diet was consumed; on day −1 a clear liquid diet was consumed. On the evening of day −1, 300-ml magnesium citrate and four bisacodyl tablets were taken. On the morning of day 0, two to three tap water enemas were given until all liquid return was clear.

Effect of oral hemoglobin.—Eleven healthy volunteers (7 methane excretors and 4 nonmethane excretors) ingested 2.5 g bovine hemoglobin in chocolate syrup three times a day

[a] Laxative-enema colonoscopy preparation from day −2–0, the day colonoscopy would be performed; days +1–+5 postpreparation recovery.

for 5 days. During a subsequent period, 3 of the same volunteers (all 3 methane excretors) ingested 6.7 g bovine hemoglobin in gelatin capsules three times a day for 5 days. Starting 7 days before hemoglobin administration and finishing several days after the last day of oral hemoglobin, we determined end-expiratory breath methane concentrations. We determined the presence of occult blood in stool specimens using the Hemoccult slide test.

Breath sample analysis.—Breath samples were tapped from the Venoject tubes and analyzed for methane on a gas chromatograph. Methane was identified and quantified by comparison of retention time and peak areas with those of standards consisting of 5 and 43.5 ppm methane in nitrogen. A sample of ambient air was collected with each pair of breath samples, and the breath methane levels were calculated as the difference between the means of the methane levels in the paired breath samples and the mean methane level of the ambient air (*9, 11*). A breath methane excretor was defined as having greater than 1 ppm methane in an end-expiratory breath sample (*9–12*).

RESULTS

Collection, storage, and transport of breath samples.—Weekly analyses showed that samples and standards could be stored for 4 weeks at room temperature without detectable loss of methane. Analysis of variance for determination of the magnitude and significance of possible sampling error and week-to-week differences demonstrated that these effects were not significant.

Effect of laxative-enema preparation.—Laxative-enema preparation reduced breath methane by 75–90% (table 1). Two subjects returned to 100% or more of pretreatment levels after 3 and 5 days; however, 2 subjects had a prolonged absence of breath methane excretion. Subject 2 returned to pretreatment levels after 21 days, and subject 1 returned after 7 months.

Effect of oral hemoglobin.—During the pretreatment week prior to oral hemoglobin, the methane excretors and nonexcretors had average breath methane levels of 12.0 ppm ± 1.9 SEM and 0.6 ppm ± 0.2 SEM, respectively. During the oral administration of 2.5 g hemoglobin three times each day, methane excretors and nonexcretors had average breath methane levels of 11.7 ppm ± 1.5 SEM and 0.2 ppm ± 0.1 SEM, respectively. The stool Hemoccult slide test became positive in 8 of 9 subjects tested within 3–8 days after the start of oral hemoglobin.

During the pretreatment week and the first 2 days of oral administration of 6.7 g hemoglobin three times each day, the stool had no occult blood. On the 3rd day, stools of all 3 subjects had occult blood. For each of the 3 methane excretors there was a slight increase in the mean breath methane excretion during the 5–9 days that stools contained

occult blood, but this increase was not statistically significant.

Patients with unresected colorectal cancer.—There was no significant difference in the frequency or the amount of breath methane excretion in patients with unresected colorectal cancer and control subjects (table 2). This finding remained true even if patients and controls on antibiotics or patients and controls on either laxatives or enemas or antibiotics within 6 days of the breath sample collection were excluded (tables 3, 4). Patients with large bowel cancer having unresected descending or sigmoid colon cancers were more likely to be breath methane excretors than patients with colorectal cancer at other sites ($0.1>P>0.05$) (table 2). Exclusion of patients and controls on antibiotics administered within 6 days of sample collected revealed that patients with descending or sigmoid colon cancers were almost twice as likely to be breath methane excretors as were patients with colorectal cancers in other locations ($0.05>P>0.01$) (table 3). The additional exclusion of patients and controls on either laxatives or enemas within 6 days of sample collection demonstrated the same trend, but this was not significant (table 4). Breath methane excretion was unrelated to age or sex (table 5).

DISCUSSION

Our retrospective study failed to confirm the observation of Haines et al. (*8*) that patients with unresected colorectal cancer are twice as likely as control subjects to be breath methane excretors. In their study, endoscopic or roentgenographic diagnostic procedures were not performed prior to breath sample collection from out-patients who came in with symptoms suggestive of large bowel cancer (personal communication). The reduced number of cancer patients excreting breath methane in our study may be due to the use of laxatives and enemas by virtually all patients before breath collection. Many of the cancer patients who did not excrete breath methane might have been methane excretors prior to laxative–enema preparation. Although bowel cleansing has been shown to decrease intracolonic methane and breath methane excretion, the length of time required to regain methane excretion has not been studied (*11*). In our study of the effect of standard colonoscopy preparation on breath methane excretion, 2 of the 4 volunteer breath methane excretors became nonexcretors for over 6 days.

Substantial differences in the anatomic distribution of colorectal cancers in the two studies might also account for the differences in our results. We have demonstrated that patients with descending or sigmoid colon cancers are twice as likely to be breath methane excretors as patients with lesions in other parts of the large bowel. A lower percentage of patients with descending and sigmoid colon cancers than was present in the study of Haines et al. (*8*) might account for our inability to confirm their observation.

Heme has been shown to be an essential in vitro growth factor for some anaerobic microflora of the human colon (*13*). Therefore, oral hemoglobin was administered for testing of the hypothesis that degraded blood from an unresected large bowel cancer provides heme to the colonic microflora, thus stimulating colonic methane production and accounting for the difference observed between cancer patients and controls of Haines et al. (*8*). In spite of delivering adequate amounts of heme to the colon, as shown by positive Hemoccult testing, no effect on breath methane excretion could be demonstrated.

The nature of the relationship between breath methane excretion and colorectal cancer remains unclear. Two additional hypotheses might account for the differences between the observation of Haines et al. (*8*) and our observation. A partial large bowel obstruction might alter the ecology of the colonic microflora, favoring the growth of methane-producing bacteria. The predominance of left-sided large bowel cancers, which are more likely to partially obstruct, in the study of Haines et al. (personal communication) compared to our study supports this hypothesis. However, our subgroup with rectal cancer did not have a higher percentage of breath methane excretors than our subgroup with cancers in the cecum, ascending colon, and transverse colon. Furthermore, none of our patients had evidence of bowel obstruction.

The second hypothesis is that breath methane excretion is a marker of the metabolism of the colonic microflora of a subgroup at greater risk for developing large bowel cancer. Studies of patients with adenomatous polyps, members of colon cancer families, and large prospective studies of the general population will be necessary to prove this hypothesis. Should this be proved to be correct, breath methane excretion might be useful for screening for the selection of a subgroup that is at increased risk for developing large bowel cancer.

N-Methyl-*N*-nitrosourea and Saccharin: Effects on Epithelium of Normal Human Urinary Bladder In Vitro[1,2,3]

Shadia El-Gerzawi,[4,5] **Barry M. Heatfield,**[4] *and* **Benjamin F. Trump**[4,6,7,8]

ABSTRACT—The effects of *N*-methyl-*N*-nitrosourea (MNU) and saccharin on the histology of normal human bladder "urothelium" (i.e., the epithelium of the urinary bladder) were studied in long-term explant cultures. In MNU-treated cultures, a dose response was observed. Single doses of 1–100 μg MNU/ml induced atypical focal hyperplasia, which reverted to a single or a double cell layer as seen in controls. Exophytic, papillary-like hyperplastic structures were noted after a single dose of 10 or 100 μg MNU/ml. In contrast to single doses, multiple doses (given every 2 wk) of MNU at 5 or 10 μg/ml resulted in striking focal proliferation of dysplastic spindle cells in as little as 6 weeks (three doses of MNU). At 0.5% saccharin, urothelium on explant surfaces resembled that of controls, except in one instance in which mild focal hyperplasia persisted. In the presence of saccharin, hyperplasia induced by a single dose of MNU persisted. Following three multiple doses of MNU in the presence of saccharin, spindle cell hyperplasia was induced similar to that seen with multiple doses of MNU alone, although nuclei appeared more pleomorphic and hyperchromatic in the presence of saccharin.—JNCI 1982; 69:577–583.

The etiology, pathogenesis, and progression of bladder cancer are poorly understood, as reflected by the continuing high rates of deaths associated with this disease in the United States (*1*). Epidemiologic studies have linked bladder cancer and occupational exposure or other exposure to environmental chemical substances such as those encountered in the dye, rubber, leather, and printing industries and in cigarette smoke (*2*). The hypothesis that these and other naturally occurring or synthetic chemicals that contaminate food, drinking water, and the atmosphere may result in bladder cancer (*3–5*) is in keeping with the prevailing opinion that 80–90% of human cancers are caused by environmental agents including chemical carcinogens (*6*). Although an association between exposure to chemicals and development of bladder cancer in humans is supported by the results of experimental studies with animal models in which various chemical agents are used in vivo (*7*), direct evidence of such an association in humans is not yet available.

The understanding of the pathogenesis and progression of bladder cancer in humans is largely based on extrapolation from in vivo animal studies, which can provide a continuum of development stages. Certain features of the animal tumor have their counterparts in the human tumor, although early, preneoplastic changes are difficult to obtain and assess in the human tumor. Despite similarities between the neoplasm in human and animal models, extrapolation from one to the other is often difficult. This has led to attempts to develop models based on human tissues. However, use of human tissue presents some unique problems. First, because of the obvious risks to the individual, exposure of human bladder "urothelium" (i.e., the epithelium of the urinary bladder) to potentially toxic or carcinogenic substances under experimental conditions can only be undertaken in vitro. Second, bladder tissue obtained at the time of surgery for neoplastic or nonneoplastic disease, usually in older individuals, is not suitable for studies of the effects of carcinogens on human bladder urothelium in vitro, because of the possibility that focal preneoplastic changes are already present in the urothelium, even though the urothelium may otherwise appear histologically normal. The presence of such changes would, of course, invalidate conclusions on the induction of neoplastic transformation in vitro following exposure to carcinogens.

In the present report, we describe the results of in vitro studies on chemical carcinogenesis in which we used bladder urothelium obtained from young individuals at the time of immediate autopsy (*8*) following accidental death. This paper represents the first attempt to study the response of normal human bladder urothelium to chemical carcinogens in vitro and to evaluate the effects of saccharin directly on human urothelial cells.

MATERIALS AND METHODS

Tissues.—Normal human bladder was obtained at immediate autopsy (*8*) of 9 male and 3 female patients who ranged in age from 16 to 33 years and who had died of accidental causes. None of the patients had any history of neoplastic disease of the bladder. The entire bladder was removed within a few minutes following somatic death, opened, and immersed in chilled L-15 (*9*) medium.

Culture conditions.—In a laminar flow hood, the mucosa of the entire bladder was carefully trimmed from the bladder wall. It was then rinsed several times in L-15 medium and cut into 0.5×1-cm pieces. Areas showing evidence of hem-

orrhage, usually as a consequence of catheterization, were excluded. Explants of the mucosa were then placed with the urothelial surface uppermost in 60-mm plastic petri dishes (Falcon Plastics, Oxnard, Calif.). The medium used was CMRL-1066 (GIBCO, Grand Island, N.Y.) supplemented with 0.1 mg hydrocortisone hemisuccinate/ml (Sigma Chemical Co., St. Louis, Mo.), 1 μg bovine recrystallized insulin/ml (Schwarz/Mann Division, Becton, Dickinson & Co., Orangeburg, N.Y.), 200 U amphotericin B/ml, 2 m*M* L-glutamine, and 5% heat-inactivated fetal calf serum (GIBCO). The culture dishes were then placed in controlled atmosphere chambers (Bellco Glass, Inc., Vineland, N.J.) and gassed for about 5 minutes with 45% O_2, 50% N_2, and 5% CO_2. The chambers were placed on rocker platforms that rocked at 10 cycles/minute, and they were incubated at 36.5–37°C. The medium and atmosphere were changed twice each week.

For our experiments, as many as 70 explants could be prepared from a single bladder. However, the number of explants from a given case was insufficient for simultaneous use in all experimental protocols. Nevertheless, enough explants were always available to permit the use of untreated explants from the same case as controls in those experiments performed.

MNU.—Explants were cultured for several days to 1 week before carcinogen treatment to allow recovery and acclimation of tissues to culture conditions. MNU (Ash-Stevens, Inc., Detroit, Mich.) was purified and provided by the National Cancer Institute, Bethesda, Md. MNU was dissolved in DMSO (Fisher Scientific Co., Springfield, N.J.). Because MNU has a short half-life, it was freshly prepared and used within 15–30 minutes (*10*). MNU was added to the culture medium at final concentrations of 1, 5, 10, or 100 μg/ml. The final concentration of DMSO in experimental and control cultures was 1%. The culture medium was always changed the day after treatment.

Specific safety procedures for protection of laboratory personnel included use of disposable gloves, masks, and gowns during preparation and handling of MNU and treatment of cultures. The exhausted medium and remaining carcinogen-containing solutions were placed in double plastic bags and incinerated.

Saccharin—A concentrated solution of saccharin (*o*-sulfobenzimide, sodium salt; Sigma Chemical Co., St. Louis, Mo.) was prepared in culture medium. The pH was adjusted, and the solution was sterilized through a 0.2-μm Nalgene filter unit (Nalgene-Sybron Co., Rochester, N.Y.). The solution of saccharin was then mixed with the medium to a final concentration of 0.02%, or 0.5%; 10% or 20% saccharin was toxic. Saccharin was added to the cultures with each change of medium.

In dosing cultures with MNU and/or saccharin in the various experiments, we used the following protocols:

1) A single dose of MNU was added to the culture medium at concentrations of 1, 10, and 100 μg/ml. Explants were sampled at 2-week intervals for 8 weeks. 2) Multiple doses of MNU were administered by the addition of the carcinogen at 2-week intervals to the culture medium at concentrations of 5 or 10 μg/ml up to 12 weeks, with final sampling at 14 weeks, 2 weeks after the last dose of MNU. 3) Saccharin was added to the culture medium at concentrations of 0.2, 0.5, 10, or 20% for 8 weeks. 4) A single dose of MNU was added to the culture medium at a concentration of 10 μg/ml; then 3 weeks later 0.5% saccharin was added, with a final sampling after 7 weeks. 5) Multiple doses of MNU were administered by the addition of the carcinogen at 2-week intervals to the culture medium (containing 0.5% saccharin) at a concentration of 5 μg/ml, with final sampling at 8 weeks, 2 weeks after the last dose of MNU.

Fixation and sampling.—The tissues were fixed immediately before culture (time 0 culture) and at the time of first treatment with MNU. Cultured explants were then sampled at 2 week intervals up to 14 weeks. In each experiment, explants were sampled 2 weeks after the last dose of MNU. All tissues were fixed in 4% formaldehyde–1% glutaraldehyde in 200 mOs*M* phosphate buffer (*11*). For light microscopy, fixed tissues were embedded in paraffin, and serial, transverse sections were cut 5 μm in thickness and stained with H & E or the AB–PAS sequence for detection of mucosubstances.

RESULTS

The results in most experiments are based on examination of explants from at least 2 patients. During the period of culture, some explants were occasionally lost due to contamination. Despite losses, three to five explants were usually available for sampling from most cases at each interval. Variability in morphologic response was noted among treated explants of the same patient under identical experimental conditions as well as among the different patients studied. In part, this variability can be attributed to the focal nature of the response. In general, examples of the morphologic responses of treated groups illustrated below represent the maximum observed.

Time 0 cultures.—Histologic examination of human urothelium before culture (time 0 cultures) revealed approximately six to eight layers of cells arranged in an ascending pattern of differentiation, from small basal cells with slightly hyperchromatic nuclei adjacent to the basement membrane, to elongated intermediate cells, and finally, to large, mature superficial cells with pale cytoplasm and abundant vacuoles at the luminal surface (fig. 1). Intermediate and superficial urothelial cells contained periodic acid–Schiff-positive granules, some of which also were Alcian blue-positive. No areas of histologic abnormalities were observed.

Control explants.—At early periods of culture (2–3 days) in control explants in the presence or absence of DMSO, urothelial cells adjacent to cut surfaces began to flatten and migrate (fig. 2). The superficial cells sometimes could be seen at the surface of some explants at this interval, but they usually sloughed and were lost. By 2 weeks, there was gradual thinning of the urothelium; small intracellular vacuoles and rounded glandlike spaces of variable size and sometimes containing mucosubstances appeared (figs. 3, 4). Mitotic figures were rare. By 4–6 weeks (fig. 5), the urothelium consisted of only one or two layers of short, columnar or cuboidal cells with only occasional glandlike spaces. Mitotic figures were rare. By the 8th week and later (fig. 6), explants were covered by a single layer of cuboidal or flattened cells, with no evidence of mucus production or presence of glandlike spaces. During culture the stroma also showed a gradual decrease in viable cells, appearing necrotic by the end of the 8th week (*see* fig. 6).

Effects of a single dose of MNU at different concentrations.—In explants of normal human urothelium exposed to a single dose of MNU at concentrations of 1, 10, or 100 µg/ml, a dose-dependent response was noted. Two weeks after a single dose of MNU (1 µg/ml), the urothelium showed areas of microscopic, focal atypical hyperplasia with foci of cellular necrosis (fig. 7). The contour of the luminal surface was irregular, and cell orientation was disturbed with occasional hyperchromatic nuclei in some cells. Glandlike spaces were present and appeared to contain necrotic cell debris (*see* fig. 8) as well as mucosubstances (AB–PAS). At a dose of 10 µg/ml, the typical hyperplasia was characterized by the formation of microscopic papillary-like proliferations of atypical urothelial cells, which frequently projected from the upper surface of explants (fig. 8). The glandlike spaces seemed larger and more numerous compared to those of the controls (*see* fig. 3) or to those in explants treated with MNU at a concentration of 1 µg/ml (*see* fig. 7). These atypical changes were more marked in explants receiving a single dose of 100 µg MNU/ml (fig. 9). Although the degree of hyperplasia and extent of necrosis varied from explant to explant, the atypical changes with numerous, large glandlike spaces were the principal features characterizing the explants. These changes eventually reverted to the more typical single cell layer seen in untreated explants (*see* fig. 6) after about 6 weeks at concentrations of 1 µg/ml and after about 6–8 weeks at concentrations of 10 or 100 µg/ml.

Effects of multiple doses of MNU at different concentrations.—Because multiple doses of MNU at a concentration of 100 µg/ml resulted in severe toxic and necrotic changes in the explants, they were discontinued. In contrast to bladder explants exposed to single doses, bladder explants exposed to multiple doses of MNU at a concentration of either 5 or 10 µg/ml over 8–14 weeks showed marked hyperplasia that appeared focally on the surface of explants. These changes consisted of multiple layers of dysplastic, spindle-shaped cells (figs. 10, 11) sometimes arranged in whorl-like configurations. The cells varied in size and shape. They possessed large, elongated nuclei, particularly in cells near the surface, and had conspicuous nucleoli. Mitotic figures were common both in the deep and superficial layers (fig. 10). Glandlike spaces were absent.

These spindle-shaped cells differed morphologically from the hyperplastic cells seen in explants following a single dose of MNU (cf. figs. 7–9). Moreover, atypical spindle cell hyperplastic changes persisted, in contrast to the lack of persistence of hyperplastic changes in explants treated with a single dose of MNU.

Effects of saccharin.—In these experiments, continuous exposure of explants to saccharin alone at concentrations of 0.2 or 0.5% resulted in only mild, if any, urothelial changes different from changes seen in untreated controls. Differences between treated cultures and controls were mainly reflected by a possible increase in the number of small glandlike structures in treated cultures. However, in one sample after 8 weeks, focal hyperplasia was noted and resembled that seen at early time periods following a single dose of MNU (fig. 12).

Effects of MNU in single or multiple doses followed by saccharin.—In explants receiving only a single dose of 10 µg MNU/ml followed 3 weeks later by continuous exposure to 0.5% saccharin for 4 weeks (total of 7 wk), urothelial changes in the form of focal atypical hyperplasias with numerous glandlike spaces containing mucosubstances were noted (fig. 13); spindle cell hyperplasia was not seen. The persistence of these changes in the presence of saccharin was dramatic in these explants compared to lesions that reverted and resembled untreated controls 6–8 weeks after a single dose of 10 µg MNU/ml alone.

In contast to the histologic effects induced by saccharin following single doses of MNU, explants exposed to as few as three multiple doses of MNU at a concentration of 5 µg/ml in the presence of 0.5% saccharin showed marked focal, atypical hyperplasia of the spindle cell type by 6 weeks (figs. 14, 15). Mitotic figures were frequently observed. These hyperplastic changes were similar to those seen in explants receiving four or five doses of MNU at a concentration of 10 µg/ml in the absence of saccharin. However, nuclei appeared more pleomorphic and hyperchromatic (fig. 15). Focal hyperplasias induced by single doses of MNU were not seen in explants exposed to multiple doses of MNU in the presence or absence of saccharin.

DISCUSSION

Our previous studies characterized the surface features of untreated human bladder urothelium by scanning electron microscopy during long-term explant culture (*12*). In the present investigation, the histologic features of untreated human bladder urothelium during long-term explant culture are consistent with our earlier observations. Overall, these studies demonstrate an early loss of mature superficial cells and survival of intermediate and basal cell types, followed by a gradual reduction in the overall thickness of the urothelium. Residual urothelial cells are probably basal cells, which are the mitotic cell component of mammalian urothelium.

In sharp contrast to untreated explant cultures, in treated explant cultures the present study has clearly demonstrated a marked focal, hyperplastic response to single or multiple doses of MNU in vitro. Two distinctive patterns of response were observed in these experiments: 1) glandular and 2) spindle cell.

The glandular pattern, induced by a single dose of MNU, was characterized by a thickening of the urothelium, with loss of cell orientation. Importantly, the surface of these focal hyperplastic changes was irregular, frequently appearing papillary in profile. In animal models and in the human, the pattern of growth of transitional cell carcinoma of the bladder in approximately 90% of the cases is papillary (*4*). Presumably, the pathogenesis of this disease involves an initial focal increase in urothelial cells followed by protrusion of hyperplastic buds into the bladder lumen. Buds contain supporting fibrovascular tissue, which eventually forms the stalk of the papillary growth. Continued proliferation of urothelial cells into the bladder lumen gives rise to papillary tumors. Epithelium, similar to normal urothelium, covers papillary tumors; invasion of the bladder wall follows increases in cell atypia and in cell numbers. Hyperplastic changes noted here after a single dose of MNU resemble early neoplastic or preneoplastic alterations in mammalian urothelium, although in vitro an internal supporting stroma and vascular supply cannot, of course, develop.

In response to multiple doses of MNU, in the presence or absence of saccharin, the second pattern of response developed, which involved a striking proliferation of spindle-shaped cells. These spindle cells resemble those comprising papillary carcinoma of the bladder [*see* (*4*)]. We have not yet obtained morphologic evidence of a progression from focal hyperplastic changes in urothelial cells in response to a single dose of MNU to spindle cell lesions seen after multiple doses of MNU, with or without the addition of saccharin. The lack of such evidence at the present time could reflect a sampling error due to the focal distribution of the lesions. Further, it remains to be determined if spindle cell lesions represent carcinoma in situ or possess invasive properties. Study by electron microscopy will be needed to fully characterize these cells and to determine their reversibility or irreversibility and neoplastic potential.

The role of the artificial sweetener saccharin in the induction of neoplasms in the human remains controversial (*13*). However, in animal models some investigators have reported that administration of chemical carcinogens, such as MNU, in small, nonneoplastic doses results in neoplastic changes in bladder urothelium if this regimen is followed by administration of other compounds that may act as promoters or cocarcinogens. For example, Hicks et al. (*14*) reported that the incidence of bladder cancer in rats receiving a single initiating, but noncarcinogenic, dose of MNU followed by a diet containing saccharin was 58% compared to an incidence of only 2% when a similar dose of MNU was administered alone. Recently, Hooson et al. (*15*) observed an increase in proliferative lesions and a shorter latent period in development of lesions in rats following a carcinogenic dose of MNU. In recent lifetime feeding studies, saccharin alone produced mild urothelial hyperplasia in male and female rats and a low incidence of bladder tumors in male rats (*16*). Similarly, Cohen et al. (*17*) reported that a diet containing another carcinogen, *N*-[4-(5-nitro-2-furyl)-2-thiazolyl]formamide, induced bladder cancer in less than 20% of rats after 6 weeks, but if administration of this carcinogen was followed by a diet containing saccharin, nearly 90% of the animals developed tumors. More recently, Fukushima and Cohen (*18*) noted an increase in the rate of DNA synthesis, which paralleled mild focal hyperplasia in rats fed saccharin. By scanning electron microscopy, pleomorphic microvilli were seen, suggestive of more than a simple regenerative response. Saccharin administered simultaneously with or after *N*-butyl-*N*-(4-hydroxybutyl)-nitrosamine has also been shown to enhance the induction of hyperplastic responses in rats (*19*, *20*). Thus, possibly acting as a weak carcinogen or promoter, at least in animal models, saccharin appears to enhance the incidence of urothelial tumors. Our observations suggest prolongation of a hyperplastic urothelium by saccharin alone and are not inconsistent with the concept of sacchrin as a weak carcinogen or promoter. In combination with multiple doses of MNU, nuclei of focal, dysplastic spindle cell hyperplasias induced in the presence of saccharin appeared more pleomorphic and hyperchromatic compared to nuclei from explants treated with MNU alone. However, further studies are needed to assess the biologic significance of these alterations.

Persistence of Transforming and Nontransforming Epstein-Barr Virus in High Passages of P3HR-1 Cell Lines[1,2,3]

Paul Gerber,[4] Dharam Ablashi,[5,6] Ian Magrath,[7] Gary Armstrong,[5] Philip Andersen,[5] *and* Luba Trach[4,8,9]

ABSTRACT—At least three laboratories have reported that the P3HR-1 line, which had originally produced transforming Epstein-Barr virus (EBV), now produces only the nontransforming variant. Studies to determine whether these findings were universal or a consequence of specific cell lines or culture conditions were undertaken in P3HR-1 cultures of identical HLA types from five sources. All of the EBV preparations derived from cell lines cultured at 32, 34, and 35°C transformed cord blood lymphocytes, whereas virus propagated at 37°C did not usually transform. Furthermore, indirect immunofluorescence revealed that a monoclonal antibody directed against transforming EBV membrane glycoprotein bound to 10–12% of the P3HR-1 cells that had been continuously propagated at 34°C, but the antibody did not bind to the same cells cultured at 37°C. Although virus expression was completely repressed in transformed cord blood cells, transforming virus could be rescued by superinfection with nontransforming P3HR-1 EBV. Cells transformed with P3HR-1 virus induced poorly differentiated lymphomas in athymic nude mice after seven or eight passages. Whether all P3HR-1 cells have the potential to produce detectable quantities of transforming virus remains to be determined.—JNCI 1982; 69:585–590.

Currently, most investigators accept that there are two major classes or "strains" of EBV, which are characterized in terms of their ability to transform human cord blood lymphocytes and to induce the EBV EA in EBV DNA-containing but EBV-nonproducing cell lines, such as Raji. All known EBV, with one exception, fall into the "transforming" group; i.e., they will transform cord blood lymphocytes or lymphocytes from EBV-seronegative donors, but they will not induce EA in Raji cells (*1–3*). The exceptional virus is that produced by the P3HR-1 cell line (*4*), a clonal derivative of the Jijoye (P3J) line originally isolated by Pulvertaft (*5*) from a Nigerian patient with Burkitt's lymphoma (table 1). Menezes et al. (*3*) and Miller et al. (*1*) were unable to demonstrate transformation with P3HR-1 virus, but this virus will readily induce EA in Raji cells (*6*).

The differences in the biologic properties of the two virus classes should permit the identification of the DNA sequences and molecular events resulting in transformation as opposed to productive infection and may therefore provide insights into the molecular basis for the oncogenic potential of EBV (*7*). Such studies, however, require stable homogeneous preparations of virus particles and are ideally performed with cloned stocks of mutant viruses that can be compared with the parental strain. In this regard and in view of the recent reports that P3HR-1 virus does not transform, it is of considerable interest that the parental cell line of P3HR-1 (P3J) released only transforming virus (*8*). Moreover, early passages of P3HR-1 appear to have released transforming virus, since cell lines that were derived by infection of cord blood cells with EBV from early isolates of P3HR-1 have been reported (table 1) (*9, 10*). Quite possibly, the P3HR-1 virus has since undergone a mutation that resulted in the loss of its transforming potential (*1*). Aya and Osato (*11*), however, have recently shown that their P3HR-1 cell line releases viruses capable of inducing DNA synthesis and EBNA in cord blood cells (table 1), both of which are associated with and are possibly a prerequisite to transformation. Aya and Osato did not, however, report the induction of continuous cell lines with P3HR-1-derived virus. The question arises, therefore, as to whether high-passage P3HR-1 cells release a mixture of viruses with different biologic properties. If so, the composition of virus preparations may vary.

In view of these findings, we have studied the P3HR-1 viruses produced by cell lines maintained in different laboratories and have examined the effect of culture conditions on the properties of the released virus particles. Virus preparations obtained from cell lines continuously cultured in separate laboratories may have different properties in any given cell line. Further, since the conditions of culture differ in different laboratories, the properties of any given virus preparation may be in part dependent on these conditions.

ABBREVIATIONS USED: EA=early antigen; EBV=Epstein-Barr virus(es); EBNA=EBV nuclear antigen; EMEM=Eagle's minimum essential medium; FCS=fetal calf serum; MA=membrane antigen; VCA=viral capsid antigen.

[8] We regret to inform readers of the untimely death of Dr. Paul Gerber. This is his last contribution to the field of Epstein-Barr virus research, an area in which he was a pioneer.

[9] We extend our thanks to Dr. Gerald Quinnan, Jr., Division of Virology, Bureau of Biologics, for making available Dr. Gerber's data, books, and laboratory materials to finish this work. We thank Dr. John S. Cole, National Cancer Institute, for providing nontransforming P3HR-1 EBV through the Resource and Logistics Program. We also thank Dr. Paul Terasaki, University of California at Los Angeles, for HLA typing of our cell lines.

Temperature may be particularly important in this regard since the amount of virus released by P3HR-1 cells is increased at low temperature. In addition, Sairenji and Hinuma (*12*) have demonstrated that the Jijoye line, the parental line of P3HR-1 (table 1), releases transforming virus at 33°C but not at 37°C. Virus release from the B95-8 cell line is not affected by the temperature of incubation (at least between 32 and 37°C).

MATERIALS AND METHODS

Cells.—The origins of P3HR-1 cells from which EBV preparations were obtained are given in table 2. The precise duration of continuous culture for each of the P3HR-1 lines is not known, but in all cases the lines had been subpassaged over several years.

Raji cells were used to assay for EA induction.

All cells were grown and maintained in RPMI-1640 medium with 10% heat-inactivated FCS, 100 U penicillin/ml, and 100 µg streptomycin/ml.

HLA.—P3HR-1 cells from different sources were typed for HLA antigens. Four of the P3HR-1 cell lines were HLA A3, B17, and BW35 [identical to that reported by Traul et al. (*10*)], and one cell line from Dr. Osato (#4 in table 2) expressed only A3. The human cord blood cell lines obtained by transformation with P3HR-1 EBV were also examined for HLA so that any contamination with P3HR-1 cells would be ruled out.

Virus preparation.—As shown in table 2, cells were routinely cultured at 37°C and then at either 32 or 35°C for virus preparation. One set of P3HR-1 cells, obtained from Dr. W. Henle, The Children's Hospital of Philadelphia, Philadelphia, Pa., was consistently carried at 34°C (5*b*, table 2).

The virus was prepared as follows: 1) P3HR-1 cells were cultured at a concentration of 5×10^5 cells/ml at 37°C and were allowed to age for 6 days at 37, 35, or 32°C. On the day of harvest, supernatants were clarified by low-speed centrifugation and then concentrated by ultrafiltration (Millipore pellicon casette system with a mol wt of 1–3 million) according to the procedure of Magrath et al. (*13*). The supernatant concentrates were then passed through a 0.45-µm nitrocellulose filter and centrifuged in an SW 27 rotor at 26°K for 1 hour. Pellets were resuspended in spent medium, sonicated for 10 seconds twice on ice, and passed again through a 0.45-µm Millipore filter. Final suspension was adjusted to a concentration factor up to 1,000. Then 1- to 3-ml aliquots of virus were stored at −70°C.

2) A monoclonal antibody was used for detection of a membrane glycoprotein associated with transforming virus for virus preparation from P3HR-1-reactive and nonreactive cells. Monoclonal antibody 2F5.6 (supplied by Dr. Gary Pearson, Mayo Clinic, Rochester, Minn.) was used for identification of cells producing transforming virus by an indirect membrane immunofluorescence technique. This antibody is directed against an antigenic determinant on the major membrane glycoprotein (320°K), which is common to transforming EBV (B95-8 and AG-876) but absent from the lytic P3HR-1 EBV (*14*). We routinely used this antibody to follow the P3HR-1 cultures to detect the MA-producing cells. This antibody failed to show MA-positive cells in P3HR-1 cells carried at 37°C, but it detected between 8 and 12% MA-positive cells in P3HR-1 cells carried at 34°C (fig. 1). Thus both 2F5.6 MA-reactive and nonreactive cells were used for virus preparation from source 5 (table 2).

P3HR-1 cells at a concentration of 1×10^6/ml from source 5 (table 2) were continuously carried at 37 and 34°C for 10 days without a change of medium. On the day of virus preparation, cells were rapidly frozen and thawed twice in a small volume of their own supernatant and then mixed with the rest of the supernatant. The supernatants were clarified at low speed, filtered through a 0.45-µm filter, and concentrated by ultracentrifugation at $70\times10^3\times g$ for 1.5 hours. The pellets were then resuspended in spent medium at a final concentration of 75-fold. The virus was stored in 1-ml vials in liquid nitrogen. The cell lines from each source were examined for VCA-producing cells. There was a greater fraction of VCA-producing cells at lower temperatures, but this number varied from one preparation to another, as previously shown by Magrath et al. (*13*) with P3HR-1, AG-876 and B95-8 EBV preparations.

(*10*), 1977: Superinfection of 6410 nonproducer cells; these cells produce EBV (transforming and nontransforming)	↓ Miller et al. (*1*), 1974: P3HR-1 virus lacks transforming activity but has EA induction of Raji cells.	↓ Menezes et al. (*3*), 1975: Biological differences between EBV strains	↓ Klein et al. (*2*), 1978: The Jijoye line differs from the P3HR-1 line in that it is susceptible to infection with P3HR-1 virus.

Assay of EBV from P3HR-1 cells by induction of EA and transformation.—For assay of EA induction, 5×10^5 Raji or LDV/7 cells showing 85% or more viability were superinfected with tenfold dilutions of virus in 1.0-ml amounts. These cells were examined for EA at 48 and 72 hours post infection for calculation of EA-inducing units according to the procedure of Henle et al. (*15*).

Transforming EBV was assayed by measurement of the ability of the virus to transform human cord lymphocytes with or without treatment with Polybrene. Cord blood mononuclear cells were treated overnight with 2 µg Polybrene/ml, washed with RPMI-1640 medium, infected with 0.2 ml of virus (5×10^6 cells/ml) in a small plastic tube (12×75 mm), and incubated at 37°C. After 2 hours, the cells were washed, fed with medium, and incubated at 37°C. Half the volume of medium was changed weekly. Transformation was judged initially by morphologic changes and later by the presence of EBNA, immortalization, and EBV DNA. The transformed cells were examined for VCA and EA production. Titers were expressed as median transformation dose per milliliter (TD_{50}/ml) based on 50% transformation (*16*). Some transformed cord blood lymphocytes were also typed for HLA antigens (table 2).

Rescue of transforming virus from P3HR-1-transformed cord blood cells.—Transforming virus was rescued from transformed cord blood cells according to the method described by Yajima et al. (*17*) with slight modification. One specific P3HR-1 virus preparation (400× concentration) obtained from Pfizer and Co., Inc., Maywood, N.J., was found to possess 10^6/ml EA-inducing titer in Raji cells by serial dilutions. This P3HR-1 EBV lot also failed to induce transformation in cord blood lymphocytes over 8 weeks. This preparation thus only possessed lytic EBV and was used for rescue experiments.

The P3HR-1 virus-transformed cord blood lymphocytes were washed three times with phosphate-free EMEM containing 2% dialyzed FCS and adjusted to contain 1×10^6 cells/ml. Cells from 10 ml of this cell suspension were pelleted, and the supernatant was discarded. Pfizer P3HR-1 EBV with an EA-inducing titer in Raji cells of 10^6 was diluted 1:5 in EMEM containing 2% dialyzed FCS, and the cord blood cells were resuspended in 1 ml of virus suspension and absorbed for 2 hours. After absorption the cells were washed three times in EMEM and resuspended in 10 ml of phosphate-free EMEM containing 2% dialyzed FCS and incubated at 37°C for 72 hours. The cells were then frozen and thawed in their supernatant, clarified, filtered through a 0.45-µm Millipore filter, and concentrated to 100× as previously described.

Nucleic acid hybridization.—EBV DNA from P3HR-1 cells (supplied by Dr. Nonoyama, Showa University Research Institute, St. Petersburg, Fla., under National Cancer Institute contract) was used for hybridization with DNA from P3HR-1-transformed cells and P3HR-1 cells grown at 37°C (5*b*; table 2) according to the method of Fresen et al. (*7*). EBV genome-negative BJAB cell DNA was used as a negative control.

Induction of tumors in athymic nude mice.—Transformed cord blood cells (10^8) in their seventh or eighth passage were injected sc into each of ten 6-week-old noninbred N:NIH(S) *nu/nu* athymic nude mice (1, 2, and 5*b*; table 2). The mice had been treated with antithymocyte serum 1 week before and 2 weeks after inoculation according to the procedure of Ablashi et al. (*18*).

RESULTS AND DISCUSSION

Properties of P3HR-1 Virus Preparations

Table 2 shows the characteristics of EBV preparations from cells aged at 32, 35, and 34°C that contained EA-inducing and EA-transforming EBV. The virus preparations (75×) from P3HR-1 cells consistently carried at 34°C contained $10^{2.5}$–$10^{4.5}$ transforming virus (6/10 attempts), but they failed to release any transforming virus at 37°C (5*b*; table 2). The virus preparations (100× or 200×) from cells aged at 32 and 35°C (1, 2, 3, 4, 5*a* and 6; table 2) always released low amounts of transforming virus ($10^{1.0}$–$10^{2.5}$), regardless of the source of the P3HR-1 cells, although preparations from cells cultured at 37°C were inconsistent in their transforming abilities. Transformation was never shown by preparations concentrated less than a hundredfold (3, 5*b*; table 2) or by a preparation obtained from Pfizer, although the Pfizer preparation was a potential inducer of EA (*see* "Materials and Methods").

Table 2 shows that cord blood cells transformed by various preparations of P3HR-1 virus had different HLA types from the P3HR-1 cell line itself, which rules out contamination of the cord blood cells with P3HR-1. The transformed cells contained EBNA and EBV DNA, but they did not express any EA or VCA.

Table 2 also shows that virus preparations from all sources were also able to induce EA, although to a variable extent. EBV preparations from 5*b* (75×) at 37 and 34°C consistently contained large amounts of EA-inducing virus ($\geq 10^{4.0}$).

Detection of Transforming Virus-Associated Antigens With a Monoclonal Antibody

Our data demonstrating the presence of transforming EBV in P3HR-1 are strongly supported by the reactivity of specific EBV monoclonal antibody. The antibody gave punctate as well as full-ring fluorescence in 10–12% of the P3HR-1 cells from 5*b*, table 2, maintained at 34°C (figs. 1A, B). It also reacted with approximately 5–7% AG-876 as well as B95-8 cells (both of which release transforming virus), but it failed to react with P3HR-1 cells continuously passaged at 37°C from 5*b* or with the P3HR-1 cell line obtained from Dr. Pearson (data not included). The antibody did not react with Raji and BJAB cells. The P3HR-1 cell line subpassaged at 34°C generally showed punctate staining of cells (fig. 1A) after 3–4 days, and as the cells were further aged, brilliant membrane fluorescence was observed (fig. 1B). Thus 2F5.6 monoclonal antibody (*14*) is a valuable reagent in distinguishing between lytic and transforming EBV as well as in monitoring the production of transforming virus.

Rescue of Transforming Virus From Cord Blood Cell Lines

A number of investigators have shown that transforming

[b] Cord blood mononuclear cells were treated with 2 μg Polybrene/ml in Ablashi's laboratory but not in Gerber's laboratory. The amount of virus recovered from cells aged at 37°C was always less (≤1.0 log) in comparison to that recovered from cells aged at 32 and 35°C (≥1.0–≤2.5 logs).

[c] Cord blood mononuclear cells from same donor were used for transformation with virus preparations from 1, 4, and 6. A separate donor was used for 2 and 3, and a third for 5.

[d] EBNA test was performed usually on days 12, 14, and 18. Cells were also examined for VCA–EA.

[e] ND=not done.

[f] Cell lines inoculated into nude mice. Tumors usually appeared between 15 and 60 days, and on the average 50% of the mice had tumors with single or multiple nodules.

virus can be obtained from EBV DNA-containing, but nonvirus-producing cell lines, such as Raji, by superinfection with P3HR-1. The released transforming virus may be a recombinant between P3HR-1 and the resident viral genomes, although simple selection and amplification of P3HR-1-derived transforming particles have not been excluded.

We therefore attempted to superinfect nonproducer cell lines, which had themselves been obtained by transforming cord blood lymphocytes with P3HR-1 virus (1 and 5*b*; table 2). The filtered cell lysates from cells superinfected with nontransforming Pfizer P3HR-1 virus preparation were able to transform cord blood cells, but they were not able to induce EA in Raji cells. Thus the rescued EBV appears to be a homogeneous preparation of transforming virus particles. This strongly suggests that P3HR-1 cell lines release mixtures of virus particles with different biologic properties. Our rescued transforming P3HR-1 virus will be useful for molecular and biologic comparisons with virus derived from B95-8 and AG-876 cell lines and putative recombinants between these viruses and P3HR-1 (*7, 16, 19, 20*). In particular, it will be important to determine whether the rescued transforming virus from P3HR-1-transformed cord blood lines is identical to that rescued from P3HR-1-superinfected

Raji cells, since this determination should reveal whether or not the second virus is a recombinant or a selected subpopulation of P3HR-1 virus.

Propagation of Transformed Cell Lines in Nude Mice

Several P3HR-1 virus-transformed human cord blood lymphocyte lines inoculated into nude mice continued to proliferate as poorly differentiated lymphomas in 50% of the animals (table 2). These tumors contained human chromosomes. The tumors in most cases were composed of a single nodule, but multiple nodules were also observed. Cultured cells from these tumors contained EBNA but no EA or VCA (*18*).

Attempts are being made to transform marmoset and stump tail monkey peripheral lymphocytes with P3HR-1-transforming virus for establishment of a high-virus-producing cell line permitting further molecular and biologic comparisons between isolates.

Our data in 5*b* of table 2 are consistent with the findings of Sairenji and Hinuma (*12*) who reported high yields of transforming EBV at 33°C but not at 37°C from Jijoye (P3J) cells. However, unlike Jijoye cells, which do not yield EA-inducing virus, P3HR-1 cells produce EA-inducing virus at both 33 and 37°C. Furthermore, our recent findings with AG-876 cells maintained at 34°C show at least 2 logs more transforming virus than is obtained from cells cultured at 37°C. Therefore, the results of Sairenji and Hinuma (*12*) and our results with respect to transforming EBV suggest that growing and culturing appropriate lines at lower temperatures markedly enhance release of transforming EBV. In P3HR-1 cell lines that produce very low amounts of transforming virus, such virus may be detectable only when cells are cultured at lower temperature.

We have shown that P3HR-1 virus from cell lines propagated in several laboratories is capable of both transformation and EA induction in Raji cells. Whether individual virus particles possess both properties, whether there is a mixture of virus particles, as has been suggested by others, or whether individual nontransforming mutants can complement each other at high multiplicity and induce transformation is unknown. However, the possibility of complementation seems very unlikely in view of the fact that at least one P3HR-1 virus preparation, that obtained from Pfizer, is unable to transform at all, in spite of the fact that it contains large amounts of virus, as demonstrated by its potent ability to induce EA in Raji cells. If there are mixtures of transforming and nontransforming properties, as our rescue experiments suggest, it would be important to determine *a*) whether individual P3HR-1 cells produce one or both kinds of virus and *b*) the nature of the difference between these particles. Cloning of cells may provide the means to answer these questions.

A Deletion in Chromosome 1 in Cells of a Transplantable Granulocytic Leukemia (GL-13) in Guinea Pigs[1,2]

Dorothy E. Moore,[3,4] **Warren H. Evans,**[3] *and* **Michael G. Mage**[3,5]

ABSTRACT—Chromosomes were examined in leukocytes from a unique transplantable granulocytic leukemia (GL-13) of strain 13 guinea pigs. The GL-13 leukemia has many similarities to human chronic myelogenous leukemia (CML). It has remained predominantly diploid after 90 transplant generations and is characterized cytogenetically by a terminal deletion of the long arm of one of the #1 pair of chromosomes. No other chromosomal abnormality was observed. These findings lend further support to the conclusion that the GL-13 leukemia may be a useful model for the study of human CML.—JNCI 1982; 69:591–594.

In 1978, Evans et al. (*1*) described a transplantable granulocytic leukemia in a 13/N guinea pig that had been fed *N*-nitroso-*N*-butylurea. To our knowledge, this is the only existing granulocytic leukemia in guinea pigs. Some of the properties of this transplantable leukemia (now referred to as GL-13 leukemia) resemble those of human CML. The leukemic granulocytes in the blood and marrow of the guinea pig show the complete range of cell maturity, and the leukemia cells infiltrating the spleen, liver, and other body organs are exclusively granulocytes and their precursors. In addition, a pronounced anemia develops and the marrow becomes hypoplastic as the normal and leukemia cells in the marrow are replaced by fibroblast-like cells. These properties raised the possibility that the GL-13 leukemia might serve as a useful model for the study of human CML.

It is now well documented that most cases of human CML are accompanied by a characteristic chromosome abnormality in the leukocytes called the "Ph^1 chromosome" (*2*). Because no cytogenetic studies have been performed yet on the GL-13 leukemia cells, we have examined the chromosomes in these cells to determine whether the GL-13 leukemia model resembles human CML in its cytogenetic properties.

MATERIALS AND METHODS

Blood culture.—The GL-13 leukemia originated in a strain 13 female guinea pig and has been passaged for 90 transplant generations. The techniques for passaging the leukemia have been described previously (*1*). To differentiate leukemia cells from normal female cells, we used only inbred male leukemic guinea pigs for cytogenetic analysis. Blood cultures were initiated according to the method of Shevach et al. (*3*) when the leukocyte count had reached a concentration of greater than 50,000/mm^3 and death of the guinea pig was imminent. Duplicate 10-ml cultures were initiated at a concentration of 1×10^6 cells/ml and incubated for 24–48 hours at 37°C with 95% air-5% Co_2. More than 7 different blood cultures from 7 different transplant generations were set up over a 3-year period, and the chromosomes of at least 20 cells per culture were examined.

Blood cultures from normal female guinea pigs were set up as controls. Phytohemagglutinin (6 µg/10 ml) was added to stimulate cell division. These cultures were incubated for 48–72 hours.

Metaphase preparation.—Colcemid was added 0–1 hour before harvest to give a final concentration of 0.25 µg/ml. Metaphase preparations were made according to standard procedures. The slides were stored at room temperature for 1 week before Giemsa banding (*4*) and R-banding (*5*).

RESULTS

A karyotype of the normal diploid chromosomes of the strain 13/N guinea pig can be seen in figure 1. The chromosomes are arranged according to the diploid guinea pig karyotype described by Whang-Peng et al. (*6*). The location of the centromere and the size of the chromosome determine the position of the chromosome. Chromosomes 1–16 have a definite short arm and are arranged in decreasing size. Because of their size, the sex chromosomes are placed after chromosome 2. Chromosomes 17–31 are acrocentric and are also arranged according to decreasing total length.

A typical leukemic karyotype can be seen in figure 2A. One of the chromosomes in pair 1 has a deletion at the end of the long arm (1q−). The other chromosome 1 of this pair is normal. There is no obvious translocation of the deleted material to other chromosomes in this karyotype or in other karyotypes that were studied. This chromosome abnormality was present in all the cells of all 7 cell passages studied. The only difference consistently found between the normal and leukemic chromosomes was the deletion in one leukemic

ABBREVIATION USED: CML=chronic myelogenous leukemia.

chromosome 1. Since the 50th transplant generation, a blast crisis similar to that seen in human CML has been associated with the terminal phase of the GL-13 leukemia (Evans W and Miller D: Submitted for publication). Leukemia cells from the blast crisis stage as well as from preblast crisis stages had karyotypes the same as the karyotype seen in figure 2A. Figure 2B shows in more detail several leukemic chromosome 1 pairs. A small amount of the dark bottom band can be seen in the deleted chromosome 1. Therefore, the terminal unstained band plus a portion of the dark band is missing. Technical difficulties encountered in obtaining well-spread chromosomes and evenly stained preparations made identification of some chromosomes in some preparations tentative. In particular, one chromosome 11 was often difficult to identify. The significance of this is unclear. Slides stained by R-banding added no additional information.

The leukemia cells have an essentially diploid number of chromosomes. In a count of 87 well-spread leukemia cells, 74 contained the normal diploid number of 64 chromosomes, 2 had 128, 1 had 123, and the remaining 10 contained less than 64. Two of such hypodiploid cells contained a dense micronuclei-like body, which may have been a condensed chromosome. No cells with normal karyotypes were found in any leukemic blood culture.

Inasmuch as others have reported differences in the chromosome patterns of rat leukemic leukocytes transplanted by different routes of injection (*7*), we compared the chromosomes of GL-13 leukemic leukocytes transplanted intraperitoneally with those transplanted subcutaneously. We could detect no differences.

DISCUSSION

The results of our chromosome analyses of the GL-13 leukemic granulocytes show that the only consistent, detectable alteration in these cells is a terminal deletion in one of the long arms of a single chromosome. No obvious translocation of the deleted portion to another chromosome was detected.

The Ph^1 chromosome, present in about 85% of the cases of human CML (*8*), was identified as a deleted chromosome 22 (*9*) with a portion of the long arm translocated to the long arm of chromosome 9 (*10*) except in less than 10% of the cases in which the translocation was to chromosomes other than 9 (*11*). In less than 1% of the cases, no translocation of the portion was found (*11-13*). These findings appear to indicate that the deletion of chromosome 22 is the crucial event related to the development of CML rather than the site of translocation (*11*).

The GL-13 leukemia may be a useful model for the study of human CML because it has hematologic similarities to human CML as previously described (*1*) and is now found to have a consistent single chromosome deletion. At present it is not known whether this anomaly is typical of guinea pig myelogenous leukemia since no other cases are available to examine in this species. Possible homology of the deletion in GL-13 leukemia to that in human CML can be examined when, in the future, gene loci are mapped for the terminal ends of the long arm of guinea pig chromosome 1 and compared to genes already known to be present on the terminal end of the long arm of human chromosome 22.

Although various viruses are known to cause breaks in chromosomes of mammalian cells (*14*), the oncornavirus type A particles, which have been found in the GL-13 tumor, have not been implicated in either chromosome breakage or in the development of leukemia. In addition, using cell-free extracts of leukemia cells, we have been unable thus far to produce leukemia in strain 13/N guinea pigs (Evans WH, Smith GH, Hsu CK: Unpublished results).

The availability of the new techniques of gene mapping, such as somatic cell hybridization, chromosome and DNA transfer into cells, and plasmid-gene amplification, should make possible future investigation of the question as to whether any of the abnormalities of granulocyte proliferation and differentiation in GL-13 leukemia are linked to the chromosomal defect described in the present study.

Establishment and Immunologic Characterization of 3-Methylcholanthrene-Induced Sarcoma Cell Lines Metastasizing Widely in Mice and Exhibiting Distinct and Selective Propensities for the Mode of Metastasis[1,2]

Yuso Kodama,[3] Toshio Seyama,[3] Kenji Kamiya,[3] *and* Kenjiro Yokoro[3,4]

ABSTRACT—Successive transplantations of metastatic secondary tumors of a 3-methylcholanthrene-induced sarcoma in (C57BL/Ka × C3H/He)F_1 male and female syngeneic mice resulted in the establishment of two unique tumor cell lines with enhanced metastatic potential. Moreover, each line showed distinct and selective propensities for the mode of metastasis. The 1101Pn tumor line, obtained by successive transplantations of metastatic pulmonary nodules, metastasized to many visceral organs via the bloodstream. Another tumor line, 1101Ln, selected by repeated transplantations of lymph node metastases, metastasized to almost all lymph nodes and to the lungs. When the metastatic pulmonary tumor of mice bearing 1101Ln was subcutaneously implanted on the backs of syngeneic mice, the tumor grew locally and eventually metastasized via the lymphatics, with systemic involvement of the lymph nodes. This finding is an indication that the intrinsic properties of tumor cells that form pulmonary metastases in 1101Ln tumor-bearing mice are distinct from those in 1101Pn tumor-bearing mice in terms of metastatic mode. The 1101Pn and 1101Ln tumor lines were nonimmunogenic or less immunogenic than the 505 tumor (the parental, nonselected tumor line). The growth and metastatic action of 505 tumors were enhanced by 400 R whole-body X-radiation, but no such effect was seen with 1101Pn tumors. Pretreatment of mice with OK-432, an immunopotentiator, retarded the growth and metastasis of 505 tumors but exerted little or no effect on 1101Pn tumors. The experimental results suggest that a tumor is composed of a heterogeneous cell population with respect to metastatic potential, metastatic mode, and tumor immunogenicity and that some intrinsic properties of the tumor cell have a primary role in the determination of the mode of cancer metastasis.—JNCI 1982; 69:595–605.

Cancer is characterized by uncontrolled growth and metastasis to distant organs. The development of metastasis involves four major sequential steps: 1) invasion of tumor cells into the surrounding tissues with penetration of blood and/or lymph vessels, 2) transport of tumor cells by blood or lymph flow, 3) arrest of the circulating tumor cells in small vascular beds of various organs or in lymph nodes, and 4) progressive growth of secondary tumors at extravascular sites. The detailed mechanism of metastasis formation is, however, largely obscure.

With regard to the mode of metastasis, tumor cells give rise to distant metastases through two routes: hematogenous and lymphogenous. Using ^{51}Cr-labeled tumor cells, Fisher and Fisher (*1, 2*) demonstrated direct communication between the blood and lymphatic circulations. They proposed that it was no longer practical to consider these routes as separate modes of neoplastic dissemination. Their conclusions, however, were drawn mainly from the anatomic point of view, and for the full understanding of metastatic action it is necessary to consider the biophysical properties of the tumor cell itself. Fidler, Nicolson, and co-workers (*3–6*), using both in vivo and in vitro selection systems, developed B16 melanoma variant lines that showed enhanced metastatic potential to the lungs. They suggested that tumor cell properties were instrumental in the outcome of metastasis.

We have established two separate tumor cell lines of MCA-induced sarcomas that metastasize in selective modes. The biologic behaviors of these tumor cell lines suggest that intrinsic properties of tumor cells are determining factors of the mode of the metastasis.

Tumor-specific antigens have been demonstrated in many experimental tumors and in some human tumors (*7–13*). Kim (*14*) showed that chemically induced rat mammary carcinomas with low immunogenicity have high metastatic potentials. We have studied the immunogenicity of established tumor cell lines and confirmed the results presented by Kim (*14*) in our murine sarcoma system.

MATERIALS AND METHODS

Animals.—Male and female 2- to 4-month-old (C57BL/Ka × C3H/He)F_1 mice, produced in our laboratory, were used throughout the study. C57BL/Ka mice, supplied by Professor H. S. Kaplan (Department of Radiology, Stanford University, Stanford, Calif.), have been maintained by brother × sister mating in our laboratory since 1964. C3H/He mice, obtained from Dr. K. Suzuki (Institute of Medical Science, Tokyo University, Tokyo, Japan), have been propagated in our laboratory since 1971. The mice were kept in metal wire cages, 6–7 mice per cage, in an air-conditioned room. They were given commercial pellets and tap water ad libitum.

Tumor.—MCA-induced fibrosarcoma was used throughout this study. A subcutaneous fibrosarcoma was induced

on the back of a female (C57BL/Ka × C3H/He)F_1 mouse by the injection of 1.0 mg MCA dissolved in olive oil. It has been maintained by serial subcutaneous transplantation on the backs of syngeneic mice. When the fibrosarcoma reached the eighth transplant generation, metastasis developed in the lungs. This feature of metastasis to the lungs has been maintained ever since.

When several pieces of tumor (2–3 mm in diameter) weighing about 30 mg are subcutaneously implanted on the backs of mice, the tumor kills the host within 50 days. There have been no sex-related differences in the growth rate and metastatic behavior of the tumor.

Successive and selective transplantation of metastatic tumors.—For the study of the characteristics of the tumor cells that form the metastatic nodules, metastatic tumors in the lung were serially subcutaneously transplanted on the backs of syngeneic mice. The method of selective transplantation of metastatic nodules is shown in text-figure 1. After transplant generation 12, metastatic tumor nodules in the lungs were cut with scissors into small blocks, 2–3 mm in diameter, and subcutaneously implanted on the backs of syngeneic mice. The recipient mice were killed at the preterminal stage, their lungs with the metastatic nodules were removed, and small pieces of nodules were again implanted on other syngeneic mice. The procedure was then repeated. At the third selective transplant generation, metastasis formation was found in the left axillary lymph node, the regional node of the grafted site. Metastasis to the same node was formed from the third to the eighth selective transplant generations. After the sixth selective transplantation, the metastatic axillary node of a female mouse, BC 1101, was cut into small blocks and subcutaneously implanted on the backs of syngeneic mice. When the tumor metastasized to the regional lymph nodes of these mice, blocks of these nodes were in turn implanted into other syngeneic mice. The procedure was repeated in the same manner as that employed for pulmonary metastatic nodules.

By continuing these procedures, we obtained two distinct metastatic tumor cell lines, both originally derived from the metastatic pulmonary tumor-grafted mouse BC 1101. We designated the pulmonary nodule line as 1101Pn and the lymph node nodule line as 1101Ln. The parental, nonselected tumor cell line was named 505.

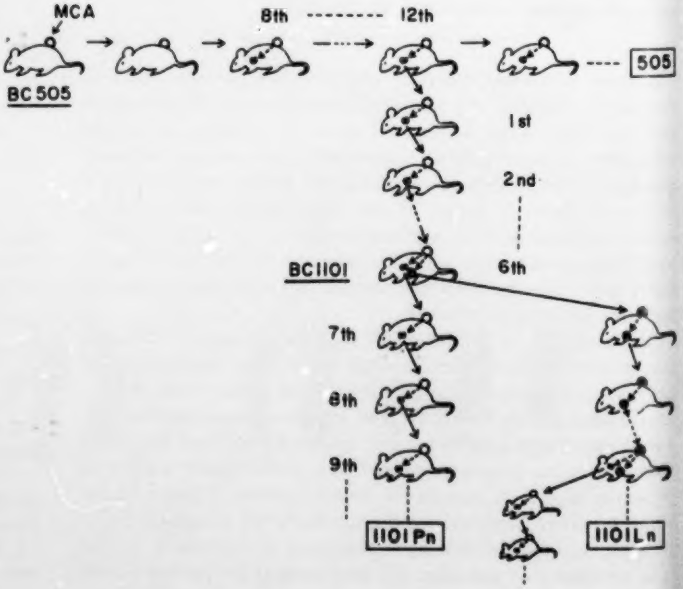
Preparation of single cell suspensions.—Single cell suspensions were obtained by trypsin digestion of tumor fragments. Tumor fragments were agitated three times for 15 minutes each on a magnetic stirrer in phosphate-buffered saline containing 0.2% trypsin at 37.0°C. Trypsinization was stopped by placement of the cell-containing flask in ice water. The tumor cell suspension was washed three times by centrifugation at 1,200 rpm for 15 minutes, and the cell pellets were resuspended in Eagle's minimum essential medium supplemented with 9% fetal calf serum. Cell concentration for injection was determined by use of a hemacytometer. The viability of the tumor cell preparation, tested by trypan blue exclusion, was usually over 95%.

Immunization with tumor cells.—Mice were immunized once with heavily irradiated tumor cells of each line. Tumor cells (2.2–2.6×10^6), irradiated with 8,000–10,000 rad of either X-rays or ^{60}Co γ-rays, were injected sc into bilateral axillary and inguinal regions and ip into syngeneic mice.

Thymectomy.—When mice were 6–7 weeks old, thymectomies were performed through a midsternal incision. The mice were under Nembutal anesthesia. The incisions were closed with silk thread.

Whole-body X-irradiation.—Mice were given whole-body X-radiation with a Toshiba KXC-18 X-ray generator at 180 kVp, 25 mA, a half value layer of 1.08 mm Cu, a focus-target distance of 60 cm, and a dose rate of 50 rad/minute.

Pretreatment with OK-432.—A streptococcal preparation, manufactured by Chugai Pharmaceutical Co., Ltd., Tokyo, and designated OK-432, has been demonstrated to possess both direct cytocidal and indirect host-mediated immunopotentiating activities (*15–18*). The content of streptococci



TEXT-FIGURE 1.—Schematic representation of the serial transplantation of metastatic tumors. Pulmonary nodules of 1101Ln-bearing mice at the ninth selective transplant generation were subcutaneously implanted on the backs of syngeneic mice. Successive transplantations of the pulmonary metastases of this line were performed in the same manner as that used for the 1101Pn line.

is expressed in KE; 1 KE corresponds to 0.1 mg dried streptococci. A fixed dose of the preparation, 0.5 KE of OK-432, dissolved in 0.2 ml physiologic saline was injected into the peritoneal cavities of syngeneic mice for 7 consecutive days (a total of 3.5 KE/mouse) before tumor implantation. Mice pretreated with OK-432 were grafted subcutaneously on the backs with tumor cells 1 day after the termination of the OK-432 treatment. In instances of iv injection of tumor cells, the injection was postponed for 5 days after OK-432 treatment to avoid the possible direct effect of OK-432 on circulating tumor cells.

Autopsy and histologic examination.—A complete autopsy was performed on every mouse. The entire body of the mouse was examined for metastases, and metastatic nodules on the surface of the lungs were counted independently by two persons with a dissecting microscope. Freshly removed organs were weighed routinely by a microbalance. For histologic examination organs were fixed in a 10% neutral Formalin solution, and paraffin-embedded tissues were cut into 5-μm-thick sections. The sections were stained with H & E. Serial sections were observed when necessary.

Analysis of results.—The results were statistically evaluated by Student's *t*-test.

RESULTS

Metastatic Spread of Cell Lines of the MCA-Induced Sarcoma

The metastatic spread of each tumor cell line is shown in tables 1 and 2. The metastatic spread of 1101Pn tended to increase as the number of transplant generations advanced (table 1). At the first and second transplant generations, the tumor metastasized only to the lungs. At the third generation, however, it metastasized to the kidneys, adrenal glands, spleen, and left axillary lymph node in addition to the lungs

[a] Beginning with the left axillary lymph node of BC 1101, metastatic nodules in the left axillary nodes of tumor-bearing mice were repeatedly implanted subcutaneously on the backs of syngeneic mice. The procedure resulted in the selection of the tumor cell line 1101Ln (table 2).

(fig. 1). Metastasis to the regional lymph node, i.e., the left axillary lymph node, was seen from the third to the eighth transplant generations. In further generations, however, no metastatic involvement of lymph nodes was seen. Instead, in later generations hematogenous metastasis began to involve the brain and the heart more consistently (figs. 2–4).

The 1101Ln, the selective cell line derived from the metastatic tumor in the left axillary lymph node of the BC 1101 mouse (6th generation; table 1), showed a distinctly different pattern of metastasis from that of 1101Pn (table 2). The metastasis of 1101Ln that developed first only in the left axillary lymph node came to involve more and more nodes and finally involved all nodes except the mesenteric lymph node (fig. 5). Conversely, no metastatic foci were observed in organs other than the lungs, except for microscopic metastases in the kidneys of the second, third, and fourth transplant generations. It is of particular interest that the extent of pulmonary metastases decreased, whereas that of lymphatic metastases increased in later transplant generations. The findings in the lungs are well reflected in the changes in lung weights which decreased steadily with serial passage (table 3).

Biologic Properties of Tumor Cells Forming Pulmonary Nodules in 1101Ln-Bearing Mice

To clarify the characteristics of tumor cells that form pulmonary nodules in 1101Ln-bearing mice, we cut into small pieces pulmonary metastases of BC 1259 and BC 1262 mice (ninth transplant generation; table 2) and implanted them subcutaneously on the backs of syngeneic mice. When the animals appeared moribund 35–40 days later, they were killed and autopsied. We found that almost all lymph nodes were systemically involved with metastatic tumors, but there was no secondary growth in other organs except the lungs (first generation; table 4).

The tumor nodules that were formed in the lungs were again subjected to successive and selective transplantations in the same manner as in the selection of the 1101Pn tumor line, to test whether it was possible to obtain a tumor cell line that showed a different mode of metastasis. To express it in a different way, we wanted to see if the metastatic mode of 1101Ln cells may be converted into that of 1101Pn cells by repeated transplantation of pulmonary nodules of 1101Ln-bearing mice. The results revealed that the metastatic pattern remained unchanged; i.e., the tumor metastasized systemically to the lymph nodes and to the lungs and only occasionally to the kidneys (table 4).

[a] No metastases were observed in the adrenal glands, spleen, brain, and heart.

[b] ++=metastasis to the left axillary and inguinal lymph nodes and occasionally to the mediastinal or retroperitoneal nodes; +++=metastasis to lymph node at the right side of the body plus ++; ++++=metastasis to almost all lymph nodes.

These results indicate that the intrinsic properties of tumor cells forming pulmonary metastases of 1101Ln-bearing mice are distinct from those of 1101Pn-bearing mice in terms of metastatic mode and that the properties are stationary in nature.

Immunogenicity of Tumor Lines

Syngeneic mice were given multiple sc and single ip injections of tumor cells of each line (505, 1101Pn, or 1101Ln), preirradiated with 8,000–10,000 rad of X-rays or ^{60}Co γ-rays. Then 7–14 days later, the immunized mice were challenged with an sc injection of live tumor cells of the respective line, and the growth of the implanted tumor was recorded. Untreated or mice treated with 400 R of whole-body X-radiation served as controls. Results are shown in table 5. When the implanted tumor cell doses were small (expts. 1, 2), there was no distinct difference in the growth of the implants in 505 and 1101Pn hosts; no tumor growth was observed in either 505 or 1101Pn hosts preimmunized with the respective tumor cells; the tumor grew only in a

TABLE 5.—*Evaluation of the immunogenicity of cell lines derived from the MCA-induced sarcoma*

Expt No.	No. of tumor cells challenged	Immune status of recipients	No. of mice with tumor/ No. challenged

		Untreated control	7/12	9/9	14/14
		Immunized[a]	1/12	8/8	15/15

[a] Immunized with heavily irradiated tumor cells.

[b] Mice were given 400 R of whole-body X-radiation a few hours before tumor challenge.

few nonimmunized 1101Pn hosts. However, in experiment 3, in which the recipients were challenged with a larger number of tumor cells, none of the mice preimmunized with either 1101Pn or 1101Ln rejected the implanted tumors. Alternatively, all but 1 of 12 mice preimmunized with 505 rejected the implants. These findings indicate a distinct difference in immunogenicity among these cell lines and show a clear inverse correlation between the immunogenicity and metastatic potential of the tumor cells, regardless of their metastatic mode.

Growth of Tumor Lines in Immunosuppressed Hosts

The growth patterns of the 505 and 1101Pn tumor lines were compared in mice treated with 400 R of whole-body X-radiation. Irradiated mice and nonirradiated controls were implanted subcutaneously with $1.24–1.27\times10^6$ tumor cells of each line; the implants were allowed to grow for 31–38 days. At autopsy, the grafted tumors were removed and weighed, and the formation of metastatic foci was carefully examined microscopically and macroscopically. The 505 line grew much faster in X-irradiated mice than in control mice, whereas 1101Pn grew equally well in both irradiated and control mice (table 6).

Metastatic Behavior of Tumor Lines in Immunosuppressed Hosts

The metastatic behavior of each tumor line was studied in thymectomized, X-irradiated mice. Recipient mice were thymectomized 7 days before they received 400 R of whole-body X-radiation. Twenty-two days after the irradiation, tumor cells of each line were injected into the tail vein. Recipients of the 505 and 1101Pn lines were killed 2 and 3 weeks after the cell injection, respectively. The shortened observation period for the 505 tumor line was due to the unexpected early deaths of the hosts. Lungs were removed and weighed, and the metastatic nodules on the surface were counted with the aid of a dissecting microscope. The other organs were also removed and examined for metastases. As shown in table 7, the formation of pulmonary metastatic nodules by 505 tumor cells was distinctly enhanced in the immunosuppressed hosts, whereas the formation of the nodules by 1101Pn was not affected by the immunologic status of the host. The lung of the immunosuppressed host, however, was slightly heavier than that of the intact host.

Effects of Pretreatment With OK-432 on Growth of Tumor Lines Subcutaneously Implanted on the Back

Subcutaneously implanted tumors were allowed to grow for 38–40 days in intact hosts or in hosts pretreated with OK-432 for 7 consecutive days so that we could observe the effect of the treatment on the tumor growth of each cell line. Table 8 shows that the growth of the 505 line tended to be inhibited by OK-432 treatment, whereas that of the 1101Pn line was not.

Effects of Pretreatment with OK-432 on Metastasis of Tumor Lines Injected Intravenously in Tail Vein

Tumor cells of each line were injected into the tail veins of intact mice or mice pretreated with OK-432. The mice were killed 21 days later, and the pattern of metastasis formation was examined. Results are shown in table 9. Again, pretreatment of OK-432 brought about an apparent decrease in both the number of pulmonary metastatic nodules and the weight of the lungs of 505 tumor-bearing hosts, whereas the effect was less marked in 1101Pn tumor-bearing hosts. The distinct response of the respective tumor-bearing hosts to OK-432 treatment may be interpreted in terms of the difference in immunogenicity of the tumor lines.

DISCUSSION

Successive transplantations of metastatic secondary tu-

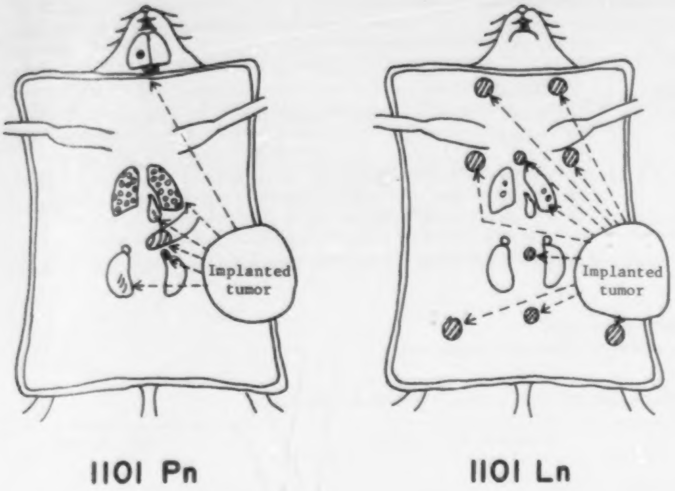
mors of MCA-induced sarcoma into syngeneic mice resulted in the establishment of unique cell lines with enhanced metastatic potential. Furthermore, each line exhibited distinct and selective propensities for the mode of metastasis. The 1101Pn tumor line, obtained by repeated transplantations of pulmonary metastases, widely metastasizes to the viscera via the bloodstream. Alternatively, the 1101Ln tumor line, derived from a metastatic nodule in the lymph node, spreads via lymphatic vessels involving almost all lymph nodes and the lungs (text-fig. 2). Both lines are the progeny of the tumor line 505 and have been obtained by repeated transplantations of each metastatic tumor originating in the lungs and in the left axillary lymph node of a single mouse (BC 1101). A study of the characteristics of tumor cells forming the pulmonary nodules of 1101Ln-bearing mice revealed that the implanted pulmonary tumors grew and eventually metastasized by the lymphogenous route, and their serial passage in syngeneic mice never resulted in alteration of the mode of metastasis. These results demonstrate that intrinsic properties of tumor cells of pulmonary nodules of 1101Ln-bearing mice are distinct from those of 1101Pn-bearing mice in terms of metastatic mode and that the properties are stable through successive in vivo transplantations.

Pressman and Simon (*19*) reported the existence of a direct anatomic connection between lymph nodes and venous channels. Fisher and Fisher (*1*) recovered iv injected ^{51}Cr-labeled tumor cells from the thoracic lymph shortly



TEXT-FIGURE 2.—Schematic representation of the metastatic spread of each cell line. The 1101Pn line metastasizes to the brain, lungs, heart, spleen, adrenal glands, and kidneys. In contrast, 1101Ln metastasizes systemically to almost all lymph nodes, i.e., the cervical, axillary, brachial, inguinal, mediastinal, and retroperitoneal lymph nodes. The 1101Ln tumor also metastasizes to the lungs to a small degree.

after injection. These reports indicate a close relationship between two vascular systems from the anatomic point of view, but they do not directly lead to the conclusion that a tumor metastasizes randomly irrespective of the nature of the tumor cell.

Fidler (*3*) was able to select B16 melanoma variant lines with enhanced metastatic potential to the lungs by in vivo and in vitro selection systems. Brunson et al. (*20*) obtained a brain-specific melanoma line by a procedure similar to that of Fidler (*3*). Brunson et al. (*20*) suggested that intrinsic properties of the tumor cell are important for the outcome of metastasis, and our results are in strong agreement with this conclusion. However, the results of the present study are not in accord with those obtained by other authors in that they have established cell lines with a particular organ specificity by repeatedly transferring secondary tumors developing in the respective organs. For example, B16 melanoma variant lines with a specific metastatic preference for lungs (*3*), brain (*20*), and liver (*21*) were selected by repeated transplantations of each metastasis. In our tumor system, however, successive transplants of pulmonary metastases did not result in selection of a cell population with a preference for only lungs but rather with a specificity for metastatic mode. A trial to obtain a tumor line with a kidney preference by repeated transfers of secondary kidney tumors was unsuccessful. It also resulted in a tumor line that metastasized in the same fashion as that of the widely metastasizing 1101Pn and 1153Pn lines (data not shown).

The metastatic tumor nodules that developed in the left axillary lymph nodes during the selection of 1101Pn (table 1) were derived from pulmonary metastases. This suggests that pulmonary metastatic nodules were composed of two tumor cell populations which differ from one another in their metastatic mode, even though pulmonary metastases consist of cells arriving at the lungs through blood vessels. We concluded, therefore, that the repeated transplantations of pulmonary nodules might have resulted in the selective adoption of a cell population with a preference for blood vessels where it survives better, minimizing the cell population that prefers the lymphatic system (table 3). In that sense, the process of the establishment of each cell line might be a selective one. Fidler (*22*) and Suzuki et al. (*23*) reported that the tumors were heterogeneous and contained many clones with different metastatic potentials. Conceivably, our tumor cell lines might have preexisted in the original 505 tumor before they were selected.

We also obtained two other tumor lines, 1153Pn and 1153Ln, from the 505 tumor by the same selection procedure as that of 1101Pn and 1101Ln. The 1153Pn and 1153Ln lines show more vigorous metastatic action than the 1101Pn and 1101Ln lines (fig. 6). Table 10 shows the results of the experiment in which 30-mg blocks of each tumor were subcutaneously implanted on the backs of syngeneic mice. A marked difference could be observed between the metastatic patterns of 1153Pn and 1153Ln: 1153Pn involved many visceral organs at a high rate of metastatic spread, whereas 1153Ln involved the lymph nodes extensively, but never metastasized to organs that were preferred by 1153Pn.

We have observed that the 1153Pn tumor line metastasized to the regional lymph nodes as well as to other organs. Consequently, we investigated the properties of tumor cells that proliferated in the regional lymph node of 1153Pn-bearing mice. Blocks of the metastatic lymph node of 1153Pn tumor-bearing mice were implanted subcutaneously on the backs of syngeneic mice. Table 11 shows that the implanted tumors eventually metastasized in the same manner as 1153Pn. This indicates that the metastatic mode of the lymph node metastases of 1153Pn tumor-bearing mice is hematogenous. The facts that 1153Pn metastasizes to the lymph nodes and its metastases consist of cells that are hematogenous imply that 1153Pn contains cell clones that show no specific preference for the metastatic mode.

When we considered the facts that tumor cell properties were maintained unchanged in spite of successive in vivo transfers and that our tumor lines contained a large cell population rigid in the selection of the metastatic mode and a small population that showed no preference for the mode, we concluded that the intrinsic properties of the tumor cell play an important role in the choice of metastatic mode.

Studies on the immunogenicity of selected lines of the MCA-induced sarcoma revealed that the widely metastasizing 1101Pn and 1101Ln tumor lines were less immuno-

genic or nonimmunogenic to the host, whereas 505, the parental tumor line that metastasized only to the lungs and only to a small extent, was distinctly immunogenic to the host. We concluded, therefore, that the metastatic potential and the immunogenicity of the tumor cell correlated well. Tumor 505 was rejected by specifically preimmunized hosts, whereas no such protection against the implanted tumor was observed with 1101Pn and 1101Ln. These findings indicate that 505 has distinct TSTA on the cell membrane, whereas no recognizable TSTA exists on the cell surfaces of 1101Pn and 1101Ln. The immunosuppressive state induced by whole-body X-irradiation facilitated the growth and metastasis of 505 but had little or no effect on 1101Pn. Pretreatment of the host with OK-432, an immunopotentiator, suppressed the local and metastatic growth of 505, but it had little or no effect on 1101Pn.

These results demonstrate that the immunogenicity of the tumor cell is one of the critical factors in determining the outcome of metastasis regardless of the metastatic mode; the lower the immunogenicity, the higher the metastatic potential of the tumor cell.

It is assumed that human tumors, which often widely metastasize in a manner similar to that of our tumor line 1101Pn or 1101Ln, might be weakly immunogenic or nonimmunogenic to the human hosts.

Our tumor cell lines are new in the sense that there is no previous record of such highly metastasizable MCA-induced sarcoma cell lines in spite of the intensive use of MCA-induced sarcomas for experiments in the past. We believe that our tumor lines are useful additions to the few spontaneously metastasizing tumor models currently in use in the study of the mechanism of cancer metastasis.

Modulation of Cell-Mediated Alloimmunity by BCG. I. Antagonism and Potentiation of Immunosuppression Caused by Cytarabine[1,2,3]

Richard I. Murahata[4,5] *and* **Malcolm S. Mitchell**[6,7,8]

ABSTRACT—The ability of iv administered BCG to antagonize immunosuppression caused by injection of the antimetabolite cytarabine (β-cytosine arabinoside; ara-C) was investigated in C57BL/6 mice. Treatment with BCG 10 days before alloimmunization with killed L1210 tumor cells decreased spleen T-cell-mediated cytolysis against allogeneic P815Y tumor cells, as measured by a short-term ^{51}Cr release assay, and potentiated immunosuppression due to ara-C. In contrast, spleen cell-mediated immunity (CMI) that was assayed by a 48-hour microcytotoxicity assay (MCA) was augmented by systemic BCG administered before alloimmunization. Pretreatment with BCG resulted in a complete and long-lasting protection against the immunosuppressive effects of ara-C on this CMI as measured by the MCA. Treatment with BCG after cytoreductive therapy resulted in a significant, although transient, reversal of immunosuppression. Depending on the type of response and thus the type of effector cell measured, BCG acts as a moderate immunosuppressive agent or a strong immunopotentiator of CMI.—JNCI 1982; 69:607–612.

BCG has been used extensively as an immunologic adjuvant. Among its reported effects are accelerated skin graft rejection (*1–3*), increased antibody production (*4*, *5*), and an augmented resistance to tumors in man (*6*, *7*) and experimental animals (*8–12*). Perhaps the most well-studied tumor model is the transplantable hepatoma in the Sewall-Wright guinea pig (*10–12*), in which tumor cell–BCG vaccines or intralesional BCG caused the regression of a significant proportion of tumors and the development of systemic immunity in the animals whose tumors regressed. These results have not been consistently observed in mice or hamsters (*13–16*), and the cellular basis of the rejection is unclear. Probably, different cellular mechanisms are involved in the rejection of intralesionally injected tumors and in the expression of systemic immunity to the tumor. The inhibition of tumor growth by systemically administered BCG (*17*, *18*) may be a manifestation of yet another effect of BCG on the host's response to a tumor.

One of the more intriguing and potentially exploitable features of BCG is its ability to reverse or protect against the immunosuppressive effects of various agents, such as 3-methylcholanthrene (*5*) or cyclophosphamide (*19*, *20*). BCG also has been reported to increase the effectiveness of high-dose therapy with cyclophosphamide in an L1210 tumor model, presumably with antagonizing immunosuppression (*17*). BCG treatment can also reverse or protect against immune complex-induced suppression of macrophage receptors for cytophilic antibody (Rao VS, Mitchell MS: Data to be published). Yet, paradoxically, BCG can induce suppressor cells that inhibit the in vitro alloimmunization of cytotoxic T-cells (*21*, *22*)—which emphasizes the modulatory rather than strictly adjuvant properties of BCG.

Our study investigated the ability of systemically administered BCG to modulate the immune response to allogeneic tumor cells in the mouse, especially in conjunction with the administration of a cytoreductive agent, ara-C.

MATERIALS AND METHODS

Mice.—Female C57BL/6 mice (H-2^b) (from The Jackson Laboratory, Bar Harbor, Maine, or Charles River Breeding Laboratories, Inc., Wilmington, Mass.) were used for the preparation of all spleen cell suspensions. Animals were 8–10 weeks old at the beginning of the experiments. Adult male (C57BL/6 × DBA/2)F_1 (B6D2F_1) mice were used for the in vivo passage of the L1210 tumor line.

Cell lines.—The L1210 leukemia, which originated in a DBA/2 mouse (H-2^d), was maintained by weekly intraperitoneal passage in B6D2F_1 mice. The P815Y mastocytoma, also of DBA/2 origin, is a long-term tissue culture line that was maintained in FM supplemented with antibiotics and 10% horse serum (M.A. Bioproducts, Walkersville, Md.). The cells growing in suspension were passaged every 2 or 3 days.

Immunization.—BCG (Tice strain; National Institutes of Health, Bethesda, Md.) was obtained as lyophilized material packaged at 5±3×10^8 viable units/ampule. One container was reconstituted with 6 ml sterile saline, and mice were given iv injections of 0.2 ml (≈0.5 mg material or 2×10^7 viable units). Mice given other doses of BCG also received

a total volume of 0.2 ml. Control mice received an equal volume of saline.

C57BL/6 mice were immunized against DBA/2 alloantigens on day 0 by an ip injection of 20×10^6 L1210 cells, which had been killed by 2,800 rad X-radiation immediately before BCG injection. This radiation dose prevented growth of L1210 cells in the syngeneic strain, as judged by the survival of the host for more than 30 days after inoculation.

Cytoreductive therapy.—The ara-C (The Upjohn Company, Kalamazoo, Mich.) was diluted to 2 mg/ml in sterile saline, and mice were given ip injections of either 20 or 40 mg/kg/day on days 3–7 after antigen administration. Control mice received an equal volume of saline.

Labeling of target cells.—Target cells for the measurement of CMI by the CRA were labeled by incubation of 5×10^6 cells/ml in FM with 0.1 mCi ^{51}Cr (200–500 Ci/g; New England Nuclear Corp., Boston, Mass.) for 30–60 minutes at 37°C. The target cells were washed four times with FM before use.

CMI as measured by CRA.—The spleen was removed aseptically and gently disrupted by hand in a glass tissue grinder. Cells were washed three times and diluted in FM-S to the desired concentration of trypan blue-excluding cells. In the CRA [used as described in (*23*)], 10^5 target cells/ml, and generally 10^7 spleen cells/ml (E:T=100:1), were incubated for 6 hours at 37°C. Specific release was calculated according to the following equation: Percent specific release$=100\times(X-C)/T$, where X is cpm released in the presence of test splenocytes, C is the release in the presence of normal lymphocytes, and T is total incorporated counts. Maximum releasable counts were 80–90%, and C was generally less than 10–15%.

CMI as measured by the MCA.—The MCA procedure was similar to that of the CRA, except for the following: *a*) The incubation period was 48 hours at 37°C in an atmosphere of 5% CO_2 in air and b) the target cells remaining were counted in a hemacytometer by light microscopy. The results are expressed as percent specific inhibition of target cell growth, which was calculated according to the following equation: Percent specific inhibition$=[1-(T/N)]\times100$, where T is the number of target cells remaining in the presence of test lymphocytes and N is the number of target cells remaining in the presence of normal lymphocytes.

Assays were performed in duplicate on samples from individual spleens. Values for CMI are the means of 3–4 different experiments, in which duplicate determinations were made on 5–8 spleens. Results were analyzed by a two-tailed Student's *t*-test. Differences with a *P*-value less than 0.05 were considered to be statistically significant.

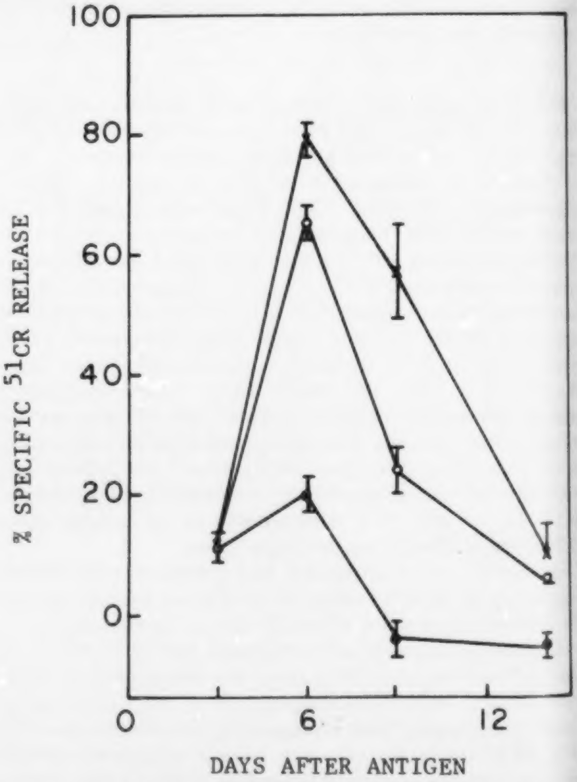
R-ATS treatment of spleen cells.—R-ATS (M.A. Bioproducts) was twice absorbed with liver homogenate from C57BL/6 mice (6 ml of a 1:3 dilution of R-ATS to 1 ml packed liver homogenate) for 30 minutes at room temperature. Spleen cells (20×10^6/ml) were added to an equal volume of R-ATS and incubated for 60 minutes at 0°C. The tubes were centrifuged, the supernatants were discarded, and the cells were resuspended to the same concentration in agarose-absorbed guinea pig complement. After incubation at 37°C for 60 minutes, the cells were centrifuged and resuspended in FM-S at the desired concentration of trypan blue-excluding cells. Treatment with R-ATS at a dilution of 1:40 killed approximately 50% of spleen cells, greater than 95% of thymocytes, and less than 10% of bone marrow cells; these cells were from several strains of mice. The response of R-ATS-treated spleen cells to concanavalin A was reduced by approximately 90%; the response to lipopolysaccharide was not decreased.

RESULTS

Preliminary experiments had established that the ip injection of 2×10^7 X-irradiated L1210 cells would elicit a submaximal immune response when the spleen cells were examined in the MCA 14 days later. This standard immunizing dose was used in all studies reported here.

Immune Response of Alloimmunized Mice

The kinetics of the development of CMI in the spleen as measured by the CRA are shown in text-figure 1. Activity was easily demonstrated by day 3. It peaked on day 6 and declined to low, but detectable, levels by day 14. Inhibition of tumor cell growth (a combination of cytotoxic and cyto-



TEXT-FIGURE 1.—Suppression of CMI by ara-C as measured by CRA. All animals were given ip injections of 20×10^6 killed L1210 cells on day 0. Mice receiving ara-C were given ip injections of the indicated dose on days 3–7. ×——×, saline; ○——○, ara-C, 20 mg/kg/day; ●——●, ara-C, 40 mg/kg/day. All data points in this and subsequent figures represent the mean of duplicate determinations on 15–18 spleens per group. *Bars* indicate ±1 SEM.

static events) as measured by the 48-hour MCA was greater than 90% on day 6, was 48% on day 15, and was still significant (30%) on day 19. The contribution of immediately cytolytic T-cells was assessed by removal of θ-positive cells before the addition of spleen cells to the assay. This treatment reduced the activity of day-6 cells from 90 to 66%, but it had no effect on the activity of cells assayed on day 14. The time period from 14 to 16 days after antigen administration was chosen for all further experiments in which the MCA was used, because this was the earliest time after immunization when the contribution of the effector cells active in the CRA (primarily cytotoxic T-cells) would not mask the effect of other cell populations active in the MCA. θ-Positive cells were not routinely removed in other experiments.

Effect of Chemotherapy With ara-C

A 5-day course of ara-C, given ip on days 3–7 after antigen administration, resulted in a dose-dependent suppression of spleen cell activity in the CRA (text-fig. 1). The activity in the MCA 14 days after immunization was also subject to dose-dependent suppression (table 1).

Effects of Immunotherapy With BCG

Spleen cells from mice that had received 0.5 mg BCG iv 10 days before alloimmunization were less active in the CRA than those from alloimmune control animals (text-fig. 2). BCG pretreatment appeared to inhibit the generation of the primary cytotoxic response, the spleen cytotoxicity being significantly suppressed on both days 9 and 14. BCG pretreatment in combination with chemotherapy was more suppressive than was chemotherapy alone.

In contrast, BCG pretreatment resulted in a significant increase in spleen cell activity as measured by the MCA (text-fig. 3). BCG pretreatment completely abrogated the suppressive effect of subsequent chemotherapy with 20 mg ara-C/kg/day. The CMI of spleen cells obtained from mice that had received combination therapy was not significantly different from that seen with cells obtained from alloimmunized control mice. Pretreatment with BCG was partially protective against the suppressive effects of the higher dose of ara-C (text-fig. 4). Immunotherapy with BCG in combination with 40 mg ara-C/kg/day resulted in spleen cell immunity intermediate between that of alloimmune control mice and mice treated with chemotherapy alone. The protective effect of BCG was observed with doses from 0.25–1.0

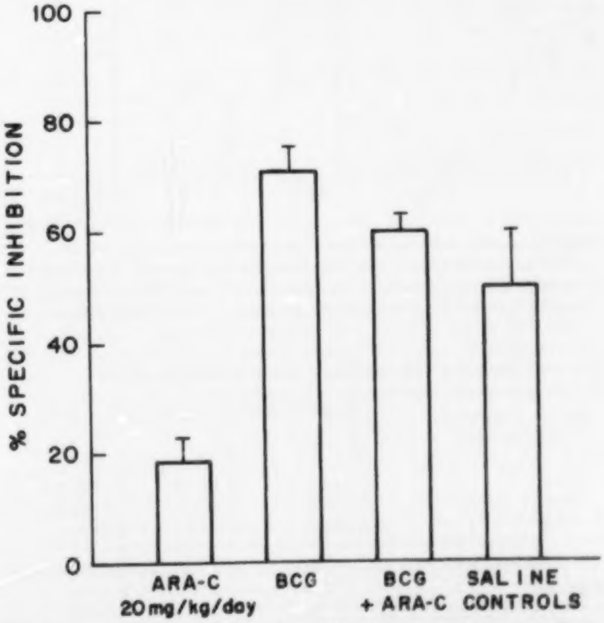
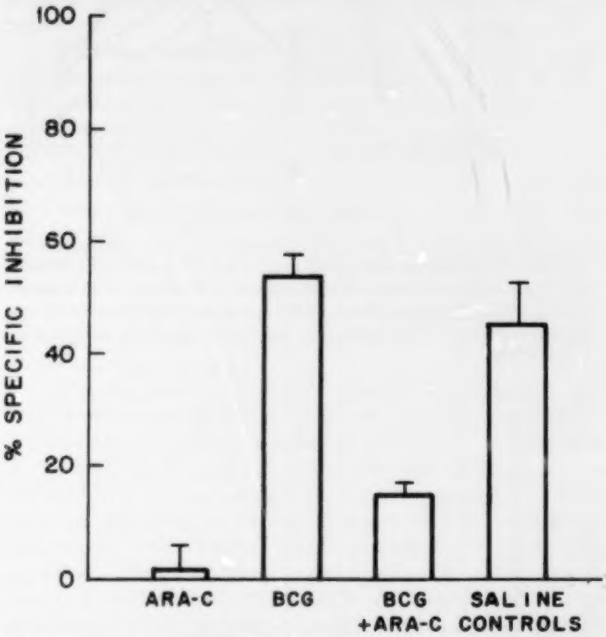
Mice receiving BCG were given iv injections of 0.5 mg on day −10. ×——×, saline; ○——○, ara-C; ●——●, BCG; □——□, ara-C and BCG.



TEXT-FIGURE 3.—Effect of BCG, in combination with low-dose ara-C, on CMI as measured by the MCA. Animals were treated as described in text-fig. 2. All animals were assayed 14 days after alloimmunization (24 days after BCG administration).

mg/mouse. There was no significant difference in the degree of protection afforded by BCG within this dose range. The relative activity among the 4 groups (alloimmune controls, and mice given chemotherapy only, immunotherapy only, or combined chemoimmunotherapy) remained consistent over E:T from 25:1 to 250:1.

The effects of BCG on spleen cell activity in the MCA was immunologically specific inasmuch as cells from all groups immunized with L1210 (*H-2^d*) had no significant inhibitory effect (11%) on the growth of a C3H (*H-2^k*) hepatoma (H-129) or an AKR (*H-2^k*) leukemia (SL-1) (table 2). These 2 tumors were sensitive targets in this assay because spleen cells obtained from C57BL/6 mice immunized against SL-1 inhibited the growth of both H-129 and SL-1. Spleen cells from mice given BCG alone were not active in the MCA at this time (24 days) after BCG administration.



TEXT-FIGURE 4.—Effect of BCG, in combination with high-dose ara-C, on CMI as measured by the MCA. Animals were treated as described in text-fig. 2, except that mice receiving ara-C were given injections of 40 mg/kg/day. All mice were killed for assay 14 days after alloimmunization.

TABLE 2.—*Specificity of spleen cells in the MCA*[a]

Source of immune effector cells	Percent inhibition of target cell growth[b]		
	P815Y	SL-1	H-129
L1210[c]	32.4±4.1	−10.0±7.8	−13.2±8.5

BCG	ara-C	Percent inhibition of target cell growth at:[b, c]	
		Day 12	Day 19
−	−	36.5±4.1	44.8±3.1
−	+[d]	15.8±3.3	16.2±6.2
+[e]	−	64.8±1.8	35.3±4.4
+[e]	+[d]	33.1±5.9	19.0±4.6

[a] All mice received ip injections of 20×10^6 killed L1210 cells on day 0.

[b] Mice were killed on day 12 or day 19, and their spleen cell activity was measured by the MCA.

[c] Values are means ± SE.

[d] 20 mg ara-C/kg/day, was administered ip on days 3–7.

[e] BCG, 0.5 mg, was administered iv on day 10 and day 13 to the indicated groups.

Because BCG administration could protect against subsequent immunosuppression by ara-C, the ability of BCG to reverse the suppressed state was investigated (table 3). ara-C was given on days 3–7; BCG was given on days 10 and 13. The suppressive effect of ara-C was transiently, but significantly, reversed by BCG. On day 12, the activity of spleen cells from animals that had received combination therapy was equal to that of cells from alloimmunized control mice and significantly greater than that seen with cells from mice treated only with ara-C. The effect of BCG therapy in this protocol was no longer apparent on day 19.

DISCUSSION

The findings of this study indicate that systemically administered BCG augments the spleen cell-mediated immune response to alloantigens measured by the MCA. Furthermore, BCG administration before ara-C inoculation completely antagonized the immunosuppressive effects of the cytotoxic drug on the cells active in this assay. When the CRA was used to measure immunity (due mainly to T-cells), BCG decreased the response to alloantigens and potentiated immunosuppression by ara-C.

The mechanisms by which systemically administered BCG interacts with chemotherapy or other modes of cytoreductive therapy may be several. Mathé et al. (*17*) suggested that BCG acts by protecting against the myelosuppressive rather than the immunosuppressive effects of cyclophosphamide. Our study supports the thesis that treatment with an immunologic adjuvant, such as BCG, in conjunction with specific immunization can act by increasing the activity of specifically armed effector cells. These effector cells may be immature members of the macrophage-monocyte family and are the subject of a companion study (*24*). The augmentation of non-T-CMI demonstrated in the present study may be related to BCG's ability to elicit other non-T-effector cells, e.g., non-specific, nonadherent cytotoxic cells (*25*), NK cells (*26*), and K cells active in antibody-dependent, cell-mediated cytotoxicity, (*27*). The lack of activity of spleen cells activated by BCG in a 6-hour CRA and the alloantigen-specific killing observed in this investigation are both inconsistent with a major role for NK cells as effectors. The relationship of the nonspecific, adjuvant-induced effectors reported earlier (*25*) to the specific effector cells reported in the present study is not clear. Specificity is probably conferred by the alloimmunization procedure added to the administration of BCG. Alternatively, the nonspecific component may be short lived and, therefore, not detected 24 days after BCG injection. In any event, BCG pretreatment in this study substantially increased the immune response to the specific tumor allograft, a true adjuvanticity. We could not determine whether BCG increased the activity per cell or simply increased the number of cells that reacted in the spleen; both are plausible. A definitive answer awaits the development of a single cell assay applicable to long-term cytotoxicity—an assay similar to those that have been developed to assess short-term cytotoxicity (*28*, *29*).

The inability of BCG pretreatment to augment cytotoxic T-cell activity, and indeed the suppression of such activity as measured in the CRA, is consistent with observations from this and other laboratories. Systemic administration of BCG in mice elicits macrophage-like cells in the spleen that inhibit proliferation in response to T-cell mitogens (*22*, *25*). Similar cells, derived from "natural suppressor" cells present in normal bone marrow, suppress the generation of cytotoxic T-cells in vitro (*21*, *22*). This, too, may well be an antiproliferative effect. Systemic administration of *Corynebacterium parvum* can also inhibit the generation of cytotoxic T-cells in vivo (*30*) and results in the generation of spleen cells that can suppress the generation of primary and memory cytotoxic T-lymphocytes in vitro (*31*). Reinisch et al. (*32*) reported that immunization of mice with allogeneic tumor cells in complete Freund's adjuvant containing mycobacteria suppressed the generation of cytotoxic T-cells while having no effect on the generation of helper or memory T-cells.

Whether the non-T cytotoxic cells discussed above are in the same family of monocytes–macrophages as the suppressor cells generated concomitantly is under investigation. In any event BCG clearly stimulates a variety of responses such that its ultimate effect on the host can be considered to be the resultant of conflicting vectors.

The ability of BCG to increase one form of CMI to tumor alloantigens and to significantly protect against the immunosuppressive effects of the clinically effective cytotoxic agent ara-C illustrates one possible cellular mechanism underlying successful immunotherapy and chemoimmunotherapy. Preliminary studies in our laboratory indicate that B6D2F$_1$ mice cured of L1210 leukemia by chemoimmunotherapy with ara-C and BCG are resistant to high-dose rechallenge [ten times the 100%-effective lethal dose (10×LD$_{100}$)], whereas mice cured by chemotherapy alone are not resistant. Further immunopharmacologic studies are required to define the cellular and molecular mechanisms by which agents such as BCG modulate host resistance.

Modulation of Cell-Mediated Alloimmunity by BCG. II. Induction of Specific, Nonadherent, Non-T-Killer Cells by BCG and Alloantigen[1,2,3]

Richard I. Murahata[4,5] *and* **Malcolm S. Mitchell**[6,7,8]

ABSTRACT—The cellular basis of the augmentation of cell-mediated immunity (CMI) by systemically administered BCG was investigated in C57BL/6 mice. BCG pretreatment potentiated the CMI to alloantigens as measured by a 48-hour microcytotoxicity assay (MCA) against P815Y tumor cells. The effector cell was not a T-cell, as demonstrated by its lack of sensitivity to antithymocyte serum and complement and its failure to kill in a short-term ^{51}Cr release assay. The effector cell also was not a classical macrophage, because it was not depleted by treatment with silica. CMI as measured by the MCA was consistently depleted by magnetic separation after incubation with carbonyl iron. The active cell(s) showed variable adherence properties. The augmentation of alloimmunity was alloantigen-specific. The specificity appeared to be due to the interaction between effector cells without inherent specificity and sensitized T-cells.—JNCI 1982; 69:613–618.

BCG is a powerful immunoadjuvant which, in appropriate doses and schedules, can potentiate both humoral (*1, 2*) and cellular (*3–5*) immune responses. It has been reported to antagonize immunosuppression due to a chemical carcinogen (*5*), cytotoxic chemotherapeutic agents (*6, 7*), and antigen–antibody complexes (*8*). Of particular interest has been its ability to augment resistance to tumors in humans (*9, 10*) and experimental animals (*11–15*). The cellular basis of many of these effects has not been clearly elucidated, although many mechanisms have been proposed including increased nonspecific trapping in the draining lymph nodes (*16*) and increased localization of specifically recruited lymphocytes (*17*).

The antitumor effects of BCG have been variously ascribed to a nonspecific activation of the reticuloendothelial system (*3, 18*), to nonspecific stimulation of lymphoid cell proliferation in lymph nodes and spleen (*1, 19*), and to a specific enhancement of the immune response (a true adjuvanticity) due to stimulation of helper–accessory cells, such as helper T-cells and macrophages (*20*). Systemic administration of BCG has been reported to result in the production of nonspecific cytotoxic cells such as macrophages (*21, 22*), K cells (*23*), and NK cells (*24*).

Spleen cell immunity, measured by the 48-hour MCA was augmented by systemic BCG in a murine allogeneic tumor model (*25*). Pretreatment with BCG resulted in complete and long-lasting protection against immunosuppression by cytarabine (*β*-cytosine arabinoside) in that model. The study reported here characterizes the cell types involved in a CMI-R evoked by alloantigens and BCG in mice. A cellular model for the ability of BCG to augment specific alloreactivity is proposed.

MATERIALS AND METHODS

Mice.—Female C57BL/6 mice (*H-2^b*) (The Jackson Laboratory, Bar Harbor, Maine, or Charles River Breeding Laboratories, Inc., Wilmington, Mass.) were used for the preparation of all spleen cell suspensions. Animals were 8–10 weeks old at the beginning of the experiments. Adult male (C57BL/6 × DBA/2)F_1 (B6D2F_1) mice were used for the in vivo passage of the L1210 tumor line.

Cell lines.—The L1210 leukemia, which originated in a DBA/2 mouse (*H-2^d*), was maintained by weekly intraperitoneal passage in B6D2F_1 mice. The P815Y mastocytoma, also of DBA/2 origin, is a long-term tissue culture line which was maintained in FM-S supplemented with antibiotics (M.A. Bioproducts, Walkersville, Md.). The cells growing in suspension were passaged every 2 or 3 days.

Immunization. BCG (Tice strain; National Institutes of Health, Bethesda, Md.) was obtained as lyophilized material packaged at 5±3 viable units/ampule. One container was reconstituted with 6 ml sterile saline, and mice were given iv injections of 0.2 ml (≈0.5 mg of material or 2×10^7 viable units). Mice given other doses of BCG also received a total volume of 0.2 ml. Control mice received an equal volume of sterile saline.

C57BL/6 mice were immunized against DBA/2 alloan-

tigens on day 0 by an ip injection of 20×10^6 L1210 cells, which had been killed by 2,800 rad X-radiation immediately before injection. This radiation dose prevented growth of L1210 cells in the syngeneic strain, as judged by the observation of the host 30 days after inoculation.

CMI as measured by the MCA.—The spleen was removed aseptically and gently disrupted by hand in a glass tissue grinder. Cells were washed three times and diluted in FM-S to the desired concentration of trypan blue-excluding cells. Spleen cells were mixed with P815Y cells at effector-to-target cell ratios (E:T) from 5:1 to 250:1, and the mixtures were incubated for 48 hours at 37°C in an atmosphere of 5% CO_2 in air. At the end of the incubation, the remaining target cells were counted in a hemacytometer by light microscopy. The results are expressed as the percent specific inhibition of target cell growth, which was calculated according to the following equation: Percent specific inhibition = $[1 - (T/N)]\times 100$, where T is the number of target cells remaining in the presence of test lymphocytes and N is the number of target cells remaining in the presence of normal lymphocytes.

Assays were performed in duplicate on samples from individual spleens. Values shown are the means of three to four experiments in which duplicate determinations were made on 5–8 spleens. Results were analyzed by a two-tailed Student's t test. Differences with a P-value less than 0.05 were considered to be statistically significant.

Fractionation of effector cells.—R-ATS treatment of spleen cells: R-ATS (M.A. Bioproducts) was twice absorbed with liver homogenate from C57BL/6 mice (6 ml of a 1:3 dilution of R-ATS to 1 ml packed liver homogenate) for 30 minutes at room temperature. Spleen cells (20×10^6/ml) were added to an equal volume of R-ATS and incubated for 60 minutes at 0°C. The tubes were centrifuged, the supernatants were discarded, and the cells were resuspended to the same concentration in guinea pig complement. After incubation at 37°C for 60 minutes, the cells were centrifuged and resuspended in FM-S at the desired concentration of trypan blue-excluding cells. Treatment with R-ATS at a dilution of 1:40 killed approximately 50% of spleen cells, greater than 95% of thymocytes, and less then 10% of bone marrow cells; these cells were from several strains of mice. The response of R-ATS-treated spleen cells to concanavalin A was reduced by approximately 90%; the response to lipopolysaccharide was not decreased.

Treatment with carbonyl iron powder: Spleen cells (4×10^6/ml) in FM-S were incubated with 4 mg carbonyl iron powder/ml (AF-special; a gift of the General Aniline and Film Corp., New York, N.Y.) for 30 minutes at 37°C, with occasional agitation. At the end of the incubation, the tube was placed between the poles of two magnets, and the phagocytic cells and excess iron were allowed to settle for 1 minute. With the magnets in place, the contents of the tube were transferred to another tube, and the process was repeated. The depleted cell population was washed once, and the appropriate concentration in FM-S was adjusted. The overall recovery of viable cells ranged from 35 to 55%; of these, approximately 85% were susceptible to lysis by R-ATS and complement. Less than 0.5% were macrophages, as determined by the acridine orange staining method (*26*).

Removal of plastic adherent cells: On 15×100-mm plastic tissue culture dishes, 6 ml spleen cells (20×10^6/ml) in FM-S were incubated for 40 minutes at 37°C. The nonadherent cells were removed by gently pipetting the medium, and they were placed on a fresh dish. The adsorption procedure was repeated three times. In one experiment, the cells were fractionated by causing them to adhere to glass of surface area equivalent to the tissue culture dishes. Less than 1% of the nonadherent cells were macrophages, as determined by the acridine orange staining technique.

Fractionation by nylon wool columns: Nylon wool columns were prepared by the method of Trizio and Cudkowicz (*27*) as modified by Bennett et al. (*28*). Spleen cells (1-5×10^8) were added to the columns, which were sealed and incubated at 37°C for 45 minutes. Nonadherent cells were recovered by dropwise elution with 25 ml prewarmed medium. Adherent cells were recovered by placing the nylon wool in 40 ml of medium and by agitating them vigorously with forceps. The cells were washed and adjusted to the desired concentration in FM-S.

X-irradiation.—The spleen cells were irradiated immediately before being placed in the assay. Various doses were used, each given at a rate of 140 rad/min on a Stabilipan (250-kV source; Siemens Corp. Medical/Industrial Groups, Iselin, N. J.).

RESULTS

Systemic administration of BCG prior to alloimmunization resulted in a marked increase in CMI as measured by the MCA (table 1). This increase was observed only in animals that were also alloimmunized. BCG administration alone had no effect. Characterization of effector cells is given below.

R-ATS-Treated Cells

Although the spleen cells were only minimally active 14 days after alloimmunization when CMI was assayed by the CRA—a test in which T-cells are at least one major type of effector cell (*26*, *29*)—the T-cells possibly were acting in a role other than that of rapidly cytolytic cells. The results of depleting T-cells by treatment with R-ATS and complement are shown in table 2. This treatment did not reduce the activity of any group in the 48-hour MCA. The increased activity in the R-ATS-treated groups probably was due to an enrichment of the non-T-effector cell population and not

to removal of a suppressor cell; however, removal of a suppressor cell as a possible cause of the increased activity cannot be ruled out.

Removal of Phagocytic or Adherent Cells

Peritoneal adherent cells (primarily macrophages) activated by BCG in the absence of specific antigen have been reported to be nonspecifically cytotoxic to transformed cell lines in vitro (*22, 30*). Macrophages are also active in several types of antibody-dependent cellular cytotoxicity reactions (*31*), and possibly they were the effector cells in our study. Macrophages were killed by the addition of 100 µg silica/ml (final concentration) (Santocel; Monsanto Co., St. Louis, Mo.) to the assay mixture (*32*). This procedure did not significantly decrease the activity of the spleen cells in the MCA (66±5% vs. 60±3%) while destroying approximately 95% of the adherent cells derived from a proteose-peptone starch-induced peritoneal exudate, as measured by their detachment from the substrate and by their being stained by trypan blue.

Inasmuch as the cytotoxic and cytostatic activities of activated macrophages have been ascribed to nonphagocytic mechanisms (*31, 33*), we thought it entirely possible that macrophages were involved but that they were acting in a nonphagocytic capacity, or that nonphagocytic or immature monocytes were involved. We, therefore, tested the effect of removal of adherent cells on the CMI mediated by spleen cells. There was no diminution of the growth inhibitory activity of the spleen cells after removal of cells adherent to plastic or glass (three serial adsorptions) (table 3). Both nylon wool-nonadherent cells and nylon wool-adherent cells had significant growth inhibitory activity (table 4). The reason for our inability to separate the effector function on the basis of adherence is not clear, although it is known that the nonadherent cells from BCG-treated spleens are qualitatively different from those obtained from the spleen of a normal mouse. Alternatively, activated suppressor macrophages that adhere tightly to the nylon wool (*34, 35*) can be removed by this procedure, which may result in increased cytotoxic activity of the nonadherent as well as the adherent fraction.

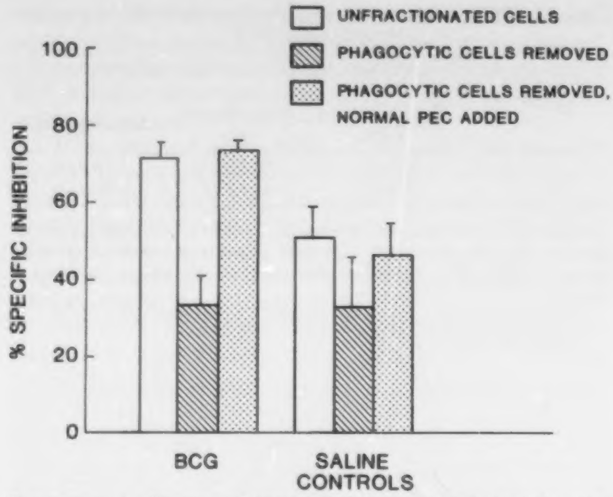
Diminution of CMI by Carbonyl Iron and Restoration by PEC

Treatment of the spleen cells with carbonyl iron and magnet reduced the number of macrophages to less than 0.5%, as determined by acridine orange staining and by phagocytosis of antibody-coated SRBC (*36*). Although this separation was most likely dependent upon adherence to, as well as phagocytosis of, the iron, for convenience the resultant fractions will be referred to as "phagocytic" and "nonphagocytic." Removal of phagocytic cells from the spleens of animals that had received BCG resulted in a significant reduction of activity (text-fig. 1). Immunity of the controls was not significantly affected by this procedure. PEC obtained from mice given ip injections of sterile proteose-peptone starch solution (2 ml of a 6% solution) significantly augmented the tumor-inhibitory activity of the nonphagocytic population (text-fig. 1). Heat-killed PEC were not able to restore the activity of immune spleen cells depleted of the phagocytic cells (table 5).

Addition of normal PEC to the unfractionated immune spleen cells led to an increased CMI activity (tables 6, 7). PEC did not inhibit tumor cell growth by themselves or when added to normal spleen cells. Inasmuch as sensitized T-cells can arm macrophages in vitro (*37*), the immune spleen cells were treated with R-ATS and complement before addition to the assay. This treatment abolished the ability of the spleen cells to cooperate with the nonimmune PEC (table 6). In the converse experiment, treatment of the PEC with R-ATS and complement did not influence the cooperation (table 7).

The spleen cells active in the MCA thus appeared to be monocyte-like cells found in sensitized mice but not in normal mice; there monocyte-like cells may have acquired



TEXT-FIGURE 1.—Decrease of growth inhibition measured by MCA after removal of spleen cells adhering to and/or ingesting carbonyl iron particles (phagocytic cells) and the restoration of activity by the addition of normal PEC, 5×10^5 cells/culture. All groups were given 20×10^6 irradiated cells and either BCG or saline, 14 days before MCA.

TABLE 5.—*Restoration of activity to nonphagocytic cells by normal PEC*[a]

BCG[b]	Percent inhibition of target cell growth[c]			
	Unfraction-ated cells	Nonphagocytic cells		
		Untreated	+ PEC[d]	+ killed PEC[e]
–	27.2±3.0	2.4±5.4	59.8±1.2	6.3±2.8
+	40.9±6.5	6.5±4.5	66.9±3.0	7.2±2.9

[a] Mice received standard immunizing dose of L1210 cells on day 0. On day 14 mice were killed, and their spleen cells were assayed for activity in the MCA, before or after fractionation by treatment with carbonyl iron and magnet.

[b] + indicates mice received 0.5 mg BCG, iv, on day −10.

[e] PEC were killed by heating to 56°C for 30 min before addition to cultures.

specificity from interaction with sensitized T-cells. Thus far our attempts to isolate a soluble cytotoxic or arming factor in this system have not been successful. Cytophilic antibody was not found in the serum nor was arming factor detectable in supernatants from spleen cell incubation mixtures. As effectors in an antibody-dependent, cell-mediated cytotoxicity assay, when antibody to SRBC was added, spleen cells from mice pretreated with BCG were not more active than those from controls. Attempts to remove any arming factors by treatment of spleen cells with trypsin were also unsuccessful. (For brevity, data from these experiments are not included.) These observations, combined with the abrogation of the ability of spleen cells to recruit specific peritoneal exudate cytotoxic cells after R-ATS treatment of the spleen, indicate that an antibody-dependent phenomenon is not involved and that the specificity is due to a direct interaction of immune T-cells and macrophages.

X-Irradiation of Effector Cells

Because macrophages are more radioresistant than lymphocytes, and activated macrophages even more so than resting cells, the effect of radiation on the effectors elicited by BCG was tested. Spleen cells were exposed to X-radiation immediately prior to the in vitro assay. A dose of 500 rad significantly reduced the CMI of control spleen cells, whereas the activity of spleen cells from animals that had received various doses of BCG and alloantigen was not affected. A 1,000-rad dose was similarly ineffective in inhibiting the CMI of BCG-treated alloimmune spleen cells.

TABLE 6.—*Effect of R-ATS treatment of immune spleen cells on their ability to cooperate with normal PEC*[a]

BCG[c]	Percent inhibition of target cell growth after X-radiation[d]			
	0 rad	500 rad	1,000 rad	3,000 rad
–	22.6±3.7	12.2±4.4	13.5±3.0	9.7±4.4
+	32.2±3.0	36.3±4.0	28.9±3.3	18.0±2.8

[a] Mice received standard immunizing dose of L1210 cells on day 0. On day 14 mice were killed for assay.

[b] Spleen cells received the indicated dose of X-radiation immediately before their addition to assay.

[c] + indicates mice received 0.5 mg BCG, iv, on day −10.

[d] Values are means ± SEM.

Not until high (3,000 rad) radiation doses were administered was the activity of the BCG-treated spleen cells reduced (table 8), again suggesting the involvement of a nonlymphocytic cell. Note, however, that activated and/or immune lymphocytes are also relatively radioresistant, and that the BCG may result in T-cell populations that are less susceptible to radiation damage.

DISCUSSION

The findings presented in this paper indicate that systemically administered BCG potentiates the spleen CMI-R to alloantigens in the mouse, as measured by the 48-hour MCA. BCG and alloantigens elicit immunologically specific cytotoxic effectors that are not T-cells but neither do they resemble classical mature macrophages. The data support the thesis that treatment with an immunologic adjuvant in conjunction with specific immunization can increase the production of specific, variably adherent, non-T-effector cells. The potentiation of specific non-T-CMI reported in this paper may be related to BCG's demonstrated ability to elicit other non-T-effectors, such as nonspecific, nonadherent spleen cytotoxic cells (*21*), NK cells (*24*), and spleen K cells (*23*). However, the lack of reactivity in the short-term CRA (*25*) and the specificity of killing we observed in this study are both inconsistent with a role for NK cells such as Wolfe and his co-workers have induced with BCG (*24*). In earlier work (*21*), BCG given alone to C57BL/6 mice caused the production of nonadherent effector cells in the spleen that inhibited P815Y mastocytoma cells in vitro. This nonspecific inhibitory activity, which also extended to $H\text{-}2^k$ tumors, was found with the MCA, but not with the CRA, 10–14 days after administration of BCG (Kinder BK, Mitchell MS: Unpublished data). In the present study, the specificity demonstrated by the spleen cells most likely was due to the alloimmunization and the longer interval between BCG inoculation and the assay. It could not be determined whether the increased immunity was due to an increased number of effector cells or an increased activity per effector cell, but both are plausible explanations.

The inability in the MCA of ATS-treated spleen cells to cooperate in the restoration of activity by normal PEC suggests that T-cells are necessary for the development of augmented specific systemic immunity after administration of BCG and antigen. However, the non-T-effector cell in the spleen appears to be the limiting factor in the expression of that immunity. Treatment of unfractionated immune spleen cells with ATS and complement did not decrease their activity in the MCA, presumably because the effector cells had already interacted with T-cells in vivo. Only when effector cells were depleted did the importance of the interaction with T-cells become manifest.

A considerable literature implicates the macrophage as an effector in antitumor immunity (*38*). In our studies a number of methods known to deplete mature macrophages had no effect on the inhibitory activity of the spleen. Poisoning the spleen cells with silica did not decrease CMI, as measured by the MCA, nor did the removal of glass- or plastic-adherent cells. Yet a good deal of evidence suggests a cell of the monocyte–macrophage lineage. When nylon-adherent cells were examined, they, as well as the nonadherent cells, showed strong activity. The presence of reactive cells in both populations may reflect a variation in the adherence properties of the same class of effector cell rather than two distinct types of cell. Bennett and Mitchell (*39*) noted a number of immature macrophages with suppressive activity in BCG spleens, which had migrated from the bone marrow. Recent evidence (Hengst JC, Mitchell MS: Unpublished data) supports this observation, inasmuch as progenitors of red blood cells, granulocytes and macrophages were found in profusion 2–3 weeks after iv inoculation with BCG. Thus poorly adherent immature macrophages and adherent more-mature macrophages might both be implicated. The decrease in activity after treatment with carbonyl iron and magnet was probably due as much to the depletion of cells adhering to the iron as to removal of cells that ingested it. This would explain the discrepancy in results with silica which poisons truly phagocytic cells.

Radioresistance also favors a cell of the macrophage series. BCG led to a considerable increase in the radioresistance of spleen CMI (as compared to the resistance induced by antigen alone), which could be due either to a greater number of radioresistant cells or to greater activation of effector cells. That the increased radioresistance is due to greater activation of effector cells is consistent with the studies of Den Otter et al. (40), who, with a 24- to 40-hour MCA, found that the resistance to ionizing radiation could be correlated with the degree of activation of the cytotoxic macrophages. Armed macrophages activated in vitro by incubation with the antigen or with lipopolysaccharide also showed increased radioresistance over that of armed unactivated cells.

The role of cytophilic antibody in this system appears to be minimal, as demonstrated by the following observations: *a*) the lack of detectable lymphocyte-dependent antibody in the sera of mice or in the supernatant of incubation mixtures and *b*) the failure of BCG to potentiate K cell activity in the spleens of treated animals. More likely, the observed specificity is conferred on the ultimate effector cell through direct interaction with immune T-cells in a manner described by other investigators (*37, 41*).

The inability of BCG pretreatment to increase cytotoxic T-cell activity measurable by the CRA is consistent with recent results from this and other laboratories. Systemic BCG elicits cells in the spleen that can inhibit T-cell proliferation to mitogens (*21*; Murahata RI: Unpublished observations) and suppress the generation of cytotoxic T-cells in vitro (*34, 35*). Reinisch et al. (*42*) reported that immunization of mice with allogeneic tumor cells in complete Freund's adjuvant suppressed the generation of cytotoxic T-cells while having no effect on the generation of helper or memory T-cells. A similar phenomenon may be occurring in our study, if the T-cells that remain capable of cooperating with macrophages are helper cells.

Alloantigenic Phenotype of Radiation-Induced Thymomas in the Mouse[1,2,3]

P. Mark Hogarth,[4] Margaret M. Henning,[4] *and* **Ian F. C. McKenzie[4]**

ABSTRACT—The alloantigenic phenotype of 21 radiation-induced thymomas is described. Monoclonal antibodies and conventional antisera, absorbed to remove contaminating antibodies, were used to test the thymomas directly for the presence of H-2, Ia, Ly-1, Ly-2, Ly-4, Ly-5, Ly-6, Ly-9, Ly-15, Thy-1, TL, and Qa-2 antigens, and for surface immunoglobulin. The phenotypes obtained by direct tests were also confirmed by absorption studies. The tumors were all of T-cell origin (Thy-1$^+$Ig$^-$) and showed a restricted heterogeneity of their cell surface phenotype, concordant with the known alloantigenic phenotypes of functional T-cells. Thus the thymomas could be classified into 7 groups based on the differing expressions of Ia, Ly-1, Ly-2, Ly-4, and Ly-6 specificities; all tumors were H-2$^+$, Ly-5$^+$, Ly-9$^+$, and Ly-15$^+$. Thus a wide variety of phenotypically diverse tumors could be detected; if these represent the clonal expansion of different functional subsets, they could provide a valuable set of functional T-cells.—JNCI 1982; 69:619–626.

T-lymphocyte functions in the mouse are mediated by various populations of T-cells that can be identified by their expression of cell surface markers (*1*). T-helper cells, T-suppressor cells, and T-cytotoxic cells can be distinguished on the basis of their Ly-1, Ly-2, Ly-3, Ly-6, and Ia phenotype (*1–3*). Thus cell surface markers have been useful in categorizing different functional T-cell subsets. Based on this, various T-cell differentiation pathways have also been suggested (*4, 5*). However, these experiments involve the depletion of Ly$^+$ lymphocytes from whole lymphoid cell suspensions, which may result in the loss of several different Ly$^+$ populations. Several approaches may be used to overcome this problem and enable the analysis of a single T-cell function. These are, first of all, creating monoclonal T-cell lines by hybridization of functional T-cells with T-cell tumors, which is, in general, unsuccessful. The second possibility, the establishment of cloned normal T-cell lines under special conditions in vitro, has been successfully achieved, although with some difficulty (*6*). Finally, T-cell tumors that grow readily in vivo or in vitro and that possess the cell surface phenotype of a particular T-cell could be induced to function as a normal T-cell of that phenotype. This approach has been successful for the study of B-cell differentiation (*7, 8*). It is also well documented that T-cell tumors can mediate functions attributed to normal cells (*9, 10*). Recently, such T-cell-like function has been demonstrated for cells of the appropriate phenotype: Ly-1$^-$2$^+$ tumor cells could specifically mediate suppression of immune function (*11*). Thus studies of the cell surface phenotype of tumors may be of great value in providing functional T-cell tumor lines.

This paper describes the testing of 21 radiation-induced thymomas with monoclonal and conventional antisera; this testing recognized 13 different cell surface antigenic systems. The aim of this study was to answer several questions: 1) Do tumors represent a monoclonal expansion of a single cell arrested at a particular stage of differentiation? 2) Are the Ly alloantigenic phenotypes the result of random gene derepression, or do they reflect the phenotype of the originally transformed T-cell? 3) What is the role of antiviral antibodies in the results obtained, and can these be overcome by the use of absorption tests or by tests with MoAb?

MATERIALS AND METHODS

Mice.—Strains of mice used for the generation of thymomas are shown in table 1. The distribution of alloantigenic specificities among these strains is also shown.

Induction and maintenance of thymomas.—Thymic lymphomas were induced in C57BL/6 mice and in related strains and in CE/J mice by repeated X-irradiation as described (*12*). Four-week-old mice received 150 rad of X-irradiation per week for 4 weeks from a Philips Ortholux machine. Thymomas appeared in 7–9 months and were maintained by serial passage in syngeneic mice by subcutaneous implantation or by ip injection and subsequent harvest of ascitic fluid. The cells were also preserved frozen in liquid nitrogen. Some tumors were not transplantable after their primary appearance, and some did not withstand cryopreservation.

Antisera.—Conventional anti-H-2 antisera used in this study were obtained from the National Institutes of Health, Bethesda, Md., and are fully described in the "Catalog of Mouse Alloantisera." The antibodies used were anti-H-2.2 (D-2), H-2.33 (D-33), H-2.23 (D-23), and H-2.32 (D-32), which were absorbed with DBA/2 lymphoid cells to remove contaminating antibodies as described below. Anti-H-2.4 (D-4) and H-2.31 (D-31) were absorbed with AKR cells, and an anti-Ia^k made as A.TH anti-A.TL was absorbed with SJL cells. Conventional anti-Ly, Thy-1, and TL antisera were made in the donor recipient combinations shown in table 2 as described (*1*). MoAb used in this study are listed in table 3.

ABBREVIATIONS USED: FcR=Fc receptor; ITT=irradiation-induced thymus tumor; MoAb=monoclonal antibody (antibodies); MuLV=murine leukemia virus; SAMIg=sheep anti-mouse immunoglobulin; sIg=surface immunoglobulin.

Absorption of antisera.—For removal of autoantibodies, antiviral antibodies, and other contaminating antibodies, all conventional antisera were absorbed. Thymus and spleen cells for absorption were obtained from 10 mice and were prepared as a single cell suspension; the cells were washed twice in medium and mixed with 0.5 ml of antiserum diluted in an equal volume of medium. The suspension was mixed and incubated for 15 minutes at room temperature, 15 minutes on ice, and then centrifuged at 500×*g* for 5 minutes. The absorbed serum was recovered, and cytotoxicity assay was performed to establish specific antibody activity.

Contaminating antibodies to known cell surface antigens were removed in the same way with the use of cells from mice with reciprocal specificity to that accorded to the antiserum (table 2). For removal of antiviral antibodies, antisera were also absorbed with lymphoid cells from aged DBA/2, NZB, or AKR mice known to express high levels of MuLV (*16, 17*) (table 2). No separate determination of antivirus titer was performed after absorption.

Serologic studies.—Direct tests: Thymoma cells were prepared as a single cell suspension and were typed directly with the use of the cytotoxicity test (*18*) with absorbed conventional antisera or SAMIg rosetting (*19*) with MoAb. We performed the tests in triplicate at one dilution of antibody (1/10–1/20) on several occasions.

Absorption studies: Absorption methods were also used to serotype tumors and were performed by the mixing of 5×10^7 tumor cells or lymphoid cells prepared as above with 100 μl antiserum at an appropriate dilution (2 tubes less than the highest dilution giving maximum lysis or rosettes). We incubated the cell-antibody mixture at room temperature for 15 minutes, then on ice for 15 minutes. The cells were removed by centrifugation at 500×*g* for 5 minutes, and the serum was then tested for residual activity on appropriate target cells. Antigen-positive and antigen-negative normal cell controls were included in the absorption as specificity controls. A positive result was obtained when absorption reduced the antibody titer by more than two tubes. Negative results showed a less than two-tube variation in titer.

Detection of FcR and sIg.—The FcR was detected with the use of sheep red blood cell–anti-sheep red blood cell complexes as described (*20*). The sIg was detected with the use of the SAMIg rosetting assay.

Nomenclature of thymomas.—The thymomas are referred to by the prefix ITT. The number after the prefix distinguishes the tumor from others that have arisen in the same strain.

RESULTS

The results of direct serologic typing of 21 radiation-induced thymomas, for 12 alloantigenic markers in C57BL/6 and related mice and CE/J mice are shown in tables 4–6. With the use of conventionally prepared antisera or MoAb, the thymomas were tested for the presence of the alloanti-

gens H-2, Ia, Ly-1, Ly-2, Ly-4, Ly-5, Ly-6, Ly-9, Ly-15, Thy-1, TL, and Qa-2, and also for sIg. Thirteen tumors were available for only a single initial test because they were either rejected on initial transplantation into syngeneic mice or could not be recovered from preservation in liquid nitrogen. Eight thymomas have been repeatedly tested by direct methods with conventional antibodies and MoAb and these results have been confirmed by absorption studies. The thymomas have been classified into groups based on similarity of Ly-1, Ly-2, Ly-4, and Ia antigenic phenotype.

Initial typing of thymomas.—In initial tests of thymomas with use of conventional alloantisera, all thymomas were positive with all the antisera (group 1, table 5). This finding implied that the antisera were contaminated with antibodies to other cell surface alloantigens (table 2) and with antiviral antibodies (*21, 22*) or autoantibodies (*23*). Contaminating autoantibodies and antibodies to other cell surface antigens were removed by absorption of the antisera with thymus and spleen cells from mice bearing the appropriate antithetical specificity, and antiviral antibodies were removed by absorption with thymus and spleen cells from mice that showed a high expression of endogenous MuLV. Antisera were considered specific when they showed: 1) a positive reaction with cells from mice carrying the allele for the specificity detected by that antiserum but not on mice congenic for that locus; and 2) no reactivity with the rat cell line W/Fu-G, which expresses high levels of the endogenous MuLV and associated antigens. All thymomas were then typed directly with the absorbed antisera by cytotoxicity assay, and where possible, these results were confirmed with the use of MoAb and SAMIg rosetting. The direct test results were then verified by absorption tests (tables 4, 5), which also confirmed the occurrence of an antigen that may be present in quantities too small to be detected by direct methods.

TABLE 3.—*MoAb used in this study*

Specificity[a]	Clone designation	Reference

[a] Ia.20 specificity is coded for by *I-A*^{b} genes only. Ia.17 specificity is coded for by genes in the *I-A* subregion of *H-2*^{k}, *H-2*^{f}, *H-2*^{r}, and *H-2*^{s}. Ia.2 specificity is coded for by *I-A*^{k} genes only.

General comments on the cell surface phenotype of the thymomas.—The conclusion that the radiation-induced tumors were of thymic origin is based on the evidence that: 1) all thymomas were Thy-1^{+} sIg^{-}; 2) approximately half of the thymomas were TL^{+}—an antigen found only on T-cells; 3) all thymomas were Ly-6^{-} and Qa-2^{-}, which implied a lack of maturity since more than 90% of the peripheral T-cells are Ly-6^{+}, Qa-2^{+}, whereas thymus cells are Ly-6^{-}, Qa-2^{-}. The data presented below also show that with the exception of 1 thymoma, ITT(1)CE, which appears to be related to a pre-T-cell, all tumors expressed Ly-2, but surprisingly most thymomas were Ly-1^{-}; i.e., most were Ly-1^{-}2^{+}. This is an unusual phenotype, which has not been detected in normal thymocytes and which is difficult to detect among peripheral T-cells (*24, 25*).

Another significant observation was that no Ly-1^{+}2^{-} thymoma was detected. The reason for this is not clear and may mean that such cells are resistant to the dose of radiation given and do not form tumors or that they are extremely radiosensitive.

Alloantigenic phenotype of thymomas.—The alloantigenic phenotype for each group of thymomas is shown in tables 4 and 5. Although each tumor in the groups bears the same Ia and Ly phenotype, there is considerable heterogeneity in the

[b] Thymomas were grouped on the basis of similarity of phenotype. Group 1 thymomas were tested only once with unabsorbed conventional antisera (*see* "Results"). They were rejected on subsequent transplantation and could not be retyped.

expression of TL within each group. Since the TL⁻ phenotype can be converted during transformation to TL⁺, it was considered that grouping the tumors on the basis of TL phenotype was unsatisfactory.

Group 1 (Ly-1⁺2⁺4⁺Ia⁺) thymomas.—These tumors arose independently at the same time and were the first to be typed by direct testing with the use of *unabsorbed* conventional antisera. All antisera gave strong positive reactions on all thymomas i.e., these cells appear H-2⁺Ia⁺Ly-1⁺Ly-2⁺Ly-4⁺Ly-6⁺Thy-1⁺TL⁺. It would appear that this phenotype is due to the presence of contaminating antibodies in the antisera. Thus the antisera were absorbed (as described in "Materials and Methods") to remove autoantibodies, antiviral antibodies, and antibodies recognizing other cell surface specificities. Following this absorption protocol, we did not observe this phenotype for any other tumor. It is therefore presumed that the positive reactions obtained with these tumors were due, in part, to contaminating antibodies. This assumption, however, cannot be formally demonstrated, because the group 1 thymomas were rejected after initial transplantation and could not be retyped with the absorbed antisera.

Group 2 (Ly-1⁺2⁺3⁻Ia⁻) thymomas.—These thymomas arose in the C57BL/6 and the *Ly-4* congenic strain

B10.C(28NX) which are both *H-2^b* (table 4). The thymomas were typed with the use of conventional antisera absorbed to remove contaminating antibodies. The 3 thymomas in this group possess the phenotype of the majority of thymocytes, i.e., Ly-$1^{+}2^{+}4^{-}$Ia^{-}, and all were Ly-5^{+}. Their possible relationship to normal thymocytes was further reinforced since they were Ly-6^{-}, as are 90% of thymocytes (*26*).

Group 3 (Ly-$1^{+}2^{+}4^{+}$Ia^{-}) thymomas.—Two thymomas, B10.A and B10.A(5R), in this group which arose in *H-2* recombinant mice had an almost identical phenotype as did the group 2 thymomas (table 4). However, unlike group 2, they were Ly-4^{+} i.e., Ly-$1^{+}2^{+}4^{+}$Ia^{-}. The results obtained with the absorbed conventional antisera were confirmed by absorption studies and by direct tests with MoAb. MoAb tests also demonstrated that these cells are Ly-9^{+}, Ly-15^{+}, and Qa-2^{-}, as are all thymocytes. This phenotype is equivalent to that seen for a subpopulation of thymocytes or mature T-cells in the periphery which expresses Ly-4 (*27*). However, because these thymomas also lacked Ly-6, the phenotypes resembles that of the thymocyte.

There is one interesting discrepancy in the Ly-1 expression on ITT(1)5R cells. As shown by the rat MoAb test that detects a framework determinant on the Ly-1 molecule common to both Ly-1.1 and Ly-1.2 strains, the cells were clearly Ly-1^{+}. However, the conventional antiserum failed to detect the Ly-1.2 specificity. This finding may be due to one of several causes. The Ly-1.2 specificity may be present in low density, and it was not detected by cytotoxicity assay, but it was detected by SAMIg rosetting, which is a more sensitive technique (*19, 28*) that may detect low Ly-1 density with the rat MoAb. Alternatively, the allotypic Ly-1.2 specificity could be absent from the Ly-1 molecule of these cells, the backbone of which is present, as detected with the MoAb test.

Group 4 (Ly-$1^{-}2^{+}4^{-}$Ia^{-}) thymomas.—This group contains the largest number of tumors, 7 in all, and they have a more "differentiated" phenotype (Ia^{-}Ly-$1^{-}2^{+}$) than the group 2 or 3 thymomas (table 5). The tumors arose in the *H-2* recombinant strains AQR and B10.A, and the *H-2^k* congenic strain B10.BR, as well as in the *Ly-2* congenic strain B6.PL(75NS). These thymomas were Ly-4^{-}, and as a measure of their immaturity they were Ly-6^{-}, but all were Ly-5^{+}. TL was variably expressed among the tumors. The ITT(1)75NS tumor was tested with the MoAb test and by absorption, which confirmed the phenotype as Ia^{-}Ly-1^{-}Ly-2^{+}Ly-4^{-}Ly-5^{+}Ly-6^{-}Ly-9^{+}Ly-15^{+}Thy-1^{+}Qa-2^{-}. The Ly-9 antigen was detected by the mouse MoAb as was the Ly-15 antigen, but Qa-2 was absent (table 5). This phenotype Ia^{-}Ly-$1^{-}2^{+}$ has been observed for several functional T-cell populations in the mouse including suppressor T-cells (*2*), and cells involved in feedback inhibition (*29*). However, knowledge on the expression of the other Ly markers on these cells is somewhat limited.

Group 5 (Ly-$1^{-}2^{+}4^{+}$Ia^{-}) thymomas.—This group comprised 3 thymomas that arose in the *H-2^k* congenic strain B10.BR and in the *Ly-4* congenic strain B10.C(28NX) (table 5). These tumors had an identical phenotype to that of the group 3 thymomas except that they were all Ly-4^{+}; i.e., they were Ia^{-}Ly-$1^{-}2^{+}4^{+}5^{+}6^{-}$, which was confirmed by testing with MoAb and by absorption tests. These tumors expressed Ly-4, which may indicate that they were somewhat more mature than the group 4 thymomas. Ly-4 is present on only a small population of thymocytes (10%), but it is present on about 90% of the peripheral T-cells (*27*). The Ly-9 and Ly-15 antigens that are present on all thymocytes were also present on the group 5 tumors. Qa-2 is absent from most thymocytes and appeared to be absent from the thymomas as well. As mentioned for the group 3 thymomas, there are several T-cell functions mediated by Ly-$1^{-}2^{+}$Ia^{-} cell types; however, the presence of Ly-4 on these functional T-cells has not been investigated.

Group 6 (Ly-$1^{-}2^{+}4^{+}$Ia^{+}) thymoma.—Although there was only 1 tumor in this group, ITT(4)B6, derived from a C57BL/6 mouse, it shows some very interesting features (table 5). The phenotype of H-2^{+}Ia^{+}-Ly-$1^{-}2^{+}4^{+}5^{+}6^{-}9^{+}15^{+}$Thy-$1^{+}$TL^{+}Qa-$2^{-}$FcR^{+} was confirmed by three different assays and reflected the phenotype of a mature peripheral T-cell. The thymoma was unique among all those tested because it was Ia^{+}Ly-$1^{-}2^{+}$. The Ia antigen expressed was detected by conventional antisera and was clearly confirmed by absorption, but the Ia antigens expressed were not Ia.20^{-} with the use of the MoAb test. As mentioned above, the Ly-$1^{-}2^{+}$ phenotype is found on several populations of functional T-cells in the periphery or is "inducible" from thymocytes (*30*). This, together with the Ly$4^{+}6^{-}$ phenotype of these cells, indicates a possible relationship with functional T-cells, possibly precursor cells, which may be Ly-6^{-} (*1*). Another remarkable finding was that this thymoma was FcR^{+}, a quality of more mature T-cells rather than of the majority of thymocytes (*31*). Ly-9, Ly-15, and Thy-1 were present on all thymocytes and peripheral T-cells. The presence of TL antigens on the surfaces of ITT(4)B6 cells was detected with conventional antisera and confirmed by absorption. Because TL antigen is restricted in its distribution to thymocytes, the phenotype of the ITT(4)B6 thymoma is totally consistent with that of a mature thymocyte.

Group 7 (Ly-$1^{-}2^{-}$Ia^{-}) thymoma.—This thymoma was derived from CE mice (*H-2^k*), and the alloantigenic phenotype appears to be that of a very primitive T-cell (table 5). After repeated testing both by direct serologic assays with conventional and monoclonal antisera and by absorption, this tumor was not found to possess the Ly-1 or Ly-2 antigens. Furthermore, the cells did not have Ly-4, Ly-6, TL, or Ia antigens, but they possessed H-2, Ly-5, Ly-15, and Thy-1. Although Ly-5 was originally thought to be restricted to T-cells (*1*), it has now been shown to have a wider distribution including pre-T-cells (*32, 33*). The distribution of Ly-15 on immature lymphoid cells has not been investigated, but its presence on this tumor suggests that it may also be a marker of pre-T-cells.

Alloantigenic phenotype of BALENTL-5.—The BALENTL-5 tumor is a thymic lymphoma derived from a BALB/c mouse treated with 1-ethyl-1-nitrosourea (*34*). This tumor was included as a control because it has been typed independently for cell surface markers in another laboratory with the use of different Ly antisera (*34*). With the use of the same reagents that were used to type the other thymomas, the BALENTL-5 tumor was found to be H-2^{+}Ia^{-}Ly-1^{-}Ly-2^{-}Ly-5^{+}Thy-1^{+}, and these results are in agreement with those of

Mathieson et al. (*34*) that showed the tumor to be Ly-1^-2^+Thy-1^+TL$^+$.

Removal of antiviral antibodies.—It is unlikely that antiviral antibodies were responsible for the phenotyping results obtained with conventional antisera. This was evident when the MoAb confirmed the positive results obtained with conventional antisera and the tumor cells could specifically absorb positive antibody activity. For confirmation that antiviral antibodies make no contribution to the positive results, the conventional antisera were further absorbed with a MuLV-Gross-infected rat leukemia that expresses cell surface antigens associated with this widespread MuLV. The absorbed antisera were tested on ITT(1)75NS and ITT(4)B6 (table 5). No differences in positive reactivity were seen between sera absorbed with lymphoid cells and those absorbed additionally with the rat leukemia. Clearly, absorption of antisera with normal lymphoid cells as described removed contaminating antibodies that may otherwise have given rise to anomalous results. This point will be fully discussed later.

Stability of phenotype.—All the thymomas were tested upon initial removal from the mouse and, where available, were repeatedly tested over 3 years. In all cases, the phenotype was found to be unchanged during successive transplants or after recovery from being frozen in liquid nitrogen.

DISCUSSION

With the use of MoAb or conventional antisera that recognize 13 cell surface antigenic systems, the cell surface phenotypes of 21 radiation-induced thymomas were determined. Several conclusions can be drawn of the results presented above: 1) The thymomas are clearly of T-cell origin but heterogeneous with respect to alloantigen expression; 2) the alloantigenic phenotypes of all thymomas are in accord with the phenotypes of normal T-cells detected by direct serologic assays or by functional assays; 3) the phenotypes found suggest that the tumor cells represent a clonal expansion of a T-cell, arrested at a certain stage of differentiation.

The remarkable feature of these thymomas is that the majority of them have the phenotype of differentiated T-cells (Ly-1^-2^+) and not the phenotype of the majority of thymocytes which are Ly-1^+2^+. This could mean that either there is a subpopulation of these "differentiated" cells within the thymus that are selectively transformed by X-irradiation, or that a peripheral T-cell is transformed by X-irradiation and then returns to the thymic microenvironment to become an overt lymphoma. The first possibility seems most likely because all the thymomas were Ly-6^- and Qa-2^-, which marked them as immature T-cells as the vast majority of thymocytes [90% of the thymocytes are Ly-6^--Qa$^-$, whereas 90% of the peripheral T-cells are Ly-6^+ Qa-2^+ (*1*)]. Furthermore, approximately half of the thymomas expressed the TL antigen, which is present on thymocytes and detectable only with difficulty on peripheral T-cells. Alternatively, expression of the Ly-1 antigen may be readily disrupted by radiation or transformation. It is difficult to determine which possibility is correct; however, the possible radiosensitivity of Ly-1 antigen expression would have to be a selective phenomenon as Ly1^+2^+ thymomas arise.

Since these phenotypes have been described for normal T-cells, it is tempting to postulate that the thymomas represent a clonal expansion of a T-cell, transformed at a particular stage of differentiation. Thus it would appear that group 2 thymomas (table 4) were derived from the pool of the majority of thymocytes which are Ly-$1^+2^+4^-$Ia$^-$, whereas group 3 (table 4) thymomas represent a somewhat more differentiated thymocyte that had acquired the Ly-4 antigen i.e., Ly-$1^+2^+4^+$Ia$^-$. However, the majority of the thymomas exhibited more "differentiated" phenotypes in terms of Ly-1 and Ly-2 expression. Group 4 thymomas are Ly-$1^-2^+4^-$Ia$^-$, whereas group 5 thymomas (table 5) are apparently more mature on the basis of their acquisition of Ly-4, i.e., Ly-$1^-2^+4^+$Ia$^-$. These phenotypes occur with cytotoxic T-cells or suppressor T-cells (*1*, *3*), or cells involved in immunoregulatory circuits (*29*, *35*).

One final point of interest is that the Ly-4 antigen was clearly selectively expressed on different thymomas. This implies that, if these tumors have arisen from T-cells at different stages of development, then Ly-4, despite its predominant B-cell distribution, may be useful in the definition of different T-cell subsets. The group 6 thymoma ITT(4)B6 (table 5) is extremely interesting, because it had a different Ly phenotype and is unlike all other thymomas in that it had Ia antigens on the cell surface and expressed a FcR; i.e., the tumor is Ly-$1^-2^+4^+$Ia$^+$FcR$^+$. These Ia antigens are also expressed on B-cells, although the T-cell expression of B-cell Ia antigens has been documented (*36*). Finally, the 1 thymoma in group 7 ITT(1)CE (table 5) appears to have been derived from a primitive T-cell, since the tumor cells express Thy-1 but do not express the other T-cell alloantigens Ly-1 or Ly-2. However, it is not possible to determine what stage of early differentiation this thymoma represents. Notwithstanding, this phenotype has been described for the natural killer cell in the mouse (*37*).

As suggested above, the phenotype of the thymomas may be accounted for by clonal expansion of a known T-cell which retains its phenotype after transformation. However, several other explanations for the observed phenotypes are possible and are discussed below.

Derepression of Inactive Cellular Genes

This is a plausible explanation of the observed phenotypes and will be difficult to resolve. There have been reports on the acquisition of foreign H-2 antigens on certain virus-transformed cells (*38*), i.e., unexpected H-2 antigens from another haplotype. This implies that the new antigens are the result of an association with the virus or are the gene products of derepressed genes. However, indirect evidence suggests that this may not be the case for thymomas in our study. There were no unusual phenotypes; that is, the phenotypes observed are all found on normal T-cells. Furthermore, if the genes were randomly derepressed, then it would be expected that there would be a random expression of antigens. Since the presence or absence of 13 different antigens was investigated, it would be expected that there are 13^2 or 169 possible antigenic phenotypes; the study demonstrated only 6 antigenic phenotypes (table 6). It is possible, however, that derepression may be selective and only certain loci are affected. However, the strong correlation between the absence of markers from these tumors that are also not present on more than 90% of the thymocytes (sIg, Ly-6, Qa-2, Ia) indicates that these phenotypes do not arise randomly. In addition, markers known to be present on all thymocytes (Ly-5, Thy-1) are present as expected. Ly-2, which is also present on 90% of thymocytes, is also found on all the thymomas.

Perhaps the only way to resolve this issue would be the testing of the thymomas for functional T-cell activity of the attempt to induce such activity that would be expected of a T-cell with this phenotype. Indeed, such functional studies have been undertaken with BALB/c mouse T-lymphomas that show restricted Ly phenotype (*11*). In this study, Ly-1^-2^+ tumor cells could suppress certain mixed lymphocyte reactions or mitogen activation, as do Ly-1^-2^+ normal cells (*1-3*).

Effective Removal of Antiviral Antibodies

There are indeed many reports of the presence of a variety of antiviral antibodies or other antibodies which bind to cell surface antigens in conventional alloantisera (*1, 21, 22, 39*). These antibodies can and do lead to anomalous results, especially when tumors grown in vitro are tested (*39, 40*). It was clear that the unabsorbed antisera used in this study contained antibodies leading to anomalous results, such as in group 1, where all tumors reacted with all the antisera. However, after absorption, this ubiquity of reaction did not occur again. The absorptions were performed tp achieve two aims: 1) the removal of antiviral and autoantibodies by absorption of antisera with thymus and spleen cells from mice whose tissues contained high levels of MuLV (NZB, AKR, DBA/2) (*16, 17*); and 2) the removal of antibodies reactive with other cell surface antigens by absorption with lymphoid cells from appropriately selected strains.

The alloantigenic phenotypes of the tumors obtained by direct testing with this absorbed antisera were real and did not include anomalous results due to antiviral or contaminating antibodies because: 1) Testing with MoAb preparations that contained no other antibody invariably agreed with the positive reactions obtained with the absorbed conventional antisera. 2) In all cases where antisera gave positive reactions, the tumor could specifically absorb antibody activity. There was no instance of a positive result with conventional antisera being negative by absorption. 3) Further absorption of the antisera with a rat leukemia, infected with MuLV-Gross (endogenous MuLV) did not change the reactivity of the antisera with the thymoma ITT(1)75NS or ITT(4)B6 (table 5). MuLV-Gross is closely related to MuLV-AKR which is wide-spread in mice (*41*), and the naturally occurring antiviral antibodies act predominantly against the major envelope glycoprotein gp70 of this virus and against cell surface antigens of infected cells associated with the virus (*41-44*). Thus if significant levels of antiviral antibodies still remained in the antisera after absorption with mouse lymphoid cells, these should have been removed by absorption with the infected rat leukemia. 4) Antiviral antibodies are highly reactive with in vitro cultured cell lines (*21, 40*), and while such reactivity is found with tumors grown in vivo, it is detectable only at high concentrations of antibody (<1/6) (*45, 46*), whereas for testing of the thymomas the antisera were used at 1/10 dilution. This finding may be due to the very rare occurrence of type C virus particles (MuLV) in in vivo grown tumors which increase in number when adapted to in vitro growth (*17*). 5) It is well documented that *radiation-induced* thymic lymphomas in C57BL/10 and related mice do not express readily detectable MuLV antigens (*41, 47, 48*). Furthermore, active viral RNA was also rarely found in radiation-induced thymomas (*41*). 6) It is conceivable that the presence of circulating antiviral antibodies in the mice leads to modulation of antigen or selection of cells that express low levels of MuLV antigens or none at all. Thus in this situation even if antiviral antibodies had not been completely removed by the procedures employed, it is unlikely that they would give rise to false-positive results.

Taken together, the evidence presented above strongly suggests that the absorption protocol for conventional antisera adequately removes contaminating antibodies and results in the production of specific, H-2, Ia, Ly, Thy-1, or TL antisera and that antiviral antibodies do not play a role in the positive reactions seen with these tumors.

The thymomas described may be of use in many areas. The selective expression of Ly antigens may provide cells for more specific immunization for Ly antibodies (conventional or monoclonal) than is possible with unfractionated spleen lymph node cells. Furthermore, if the thymomas represent transformed normal T-cells from a particular subpopulation, they may be useful as immunogens to define new antigens specific for that particular subpopulation. In addition, the possibility that these thymomas represent T-cells at a particular stage of differentiation could make them useful for the study of normal T-cell functions: killing, suppression, or factor elaboration. The production of suitable clones of normal T-cells is difficult but can be achieved. Attempts at the production of T-cell hybridomas have largely been unsuccessful. Thus the provision of readily transplantable, stable, and functional T-cell tumors would be of great benefit to cellular immunologists.

Finally, the advantages of the use of MoAb are clearly seen with the typing of tumors. Although with one exception there were no differences between typing with conventional or monoclonal antisera, the conventional sera were difficult to produce and contained other antibodies that gave rise to anomalous results. Conventional antisera therefore required extensive absorption that resulted in a concomitant loss of specific antibody activity. The use of the MoAb overcame these problems and greatly simplified serotyping of the thymomas.

Formation of Symbiotic Complex by Microenvironment-Dependent Mouse Leukemias and Thymic Epithelial Reticular Cells[1,2]

Yoshimi Nishi,[3] **Kazuhiro Yoshikawa,**[4] **Hiroshi Hiai,**[5,6] **Kunihiro Notake,**[4] **Hayase Shisa,**[7] *and* **Yasuaki Nishizuka**[5,8]

ABSTRACT—Developing thymic leukemias of the mouse have been assumed to form symbiotic complexes with thymic microenvironments. This symbiosis is morphologically based on pseudoemperipolesis (PEMP). The mechanism of the association of microenvironment-dependent leukemia cells with thymic epithelial reticular cells (TER) was analyzed in vitro by scanning electron microscopy, microcinematography, and a quantitative assessment of PEMP. PEMP was a consequence of active locomotion of the leukemia cells, with TER passively accepting the leukemia cells' "crawling" under their cytoplasm. The integrity of the cytoskeletal system of both cells was essentially required for PEMP, since cytochalasins and colchicine were highly inhibitory to PEMP. The mechanism of action of these compounds was probably dual: inhibition of the locomotive movements of the leukemia cells. A similar inhibition of PEMP was also observed with the tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate—JNCI 1982; 69: 627–637.

TER are the major cellular components of thymic microenvironments supporting differentiation and proliferation of thymocytes, which are progeny of migrating prethymocytes from the hematopoietic compartment. The function of TER is mediated at least in part by soluble factors elaborated by TER, and several biologically active substances have been identified (*1*). In contrast, the cell interaction involving close cell contact is also suggested to play a role in supporting differentiation and proliferation of thymocytes (*2*). Wekerle et al. (*3*) isolated the lymphoepithelial cell complexes from the normal murine thymus, in which lymphoid cells are localized in cytoplasmic caveolae of Ia determinant-bearing TER. From leukemic thymuses, we have shown that morphologically similar complexes of leukemic lymphocytes and TER can be isolated in vitro, and from such complexes the symbiotic cell lines are consistently obtained, in which leukemia cells depend on occasional contact with TER for their in vitro survival and growth (*4*). The leukemia cells in such cultures are frequently observed to be confined to a space between the cytoplasm of glass-adherent TER and the substrate. We have defined this form of cell interaction as PEMP (*4, 5*) to distinguish it from true "emperipolesis" (*6*) involving actual invasion of viable cells into other cells or cytophagocytosis. Although the biological significance of PEMP is still obscure, PEMP has been observed not only in symbiotic leukemias but also rather widely between various hematolymphoid cells and TER or other stromal cells [(*5*); Hiai H, Nakamura H, Kaneshima H, Nishi Y, Sato C, Nishizuka H: In preparation]. Conceivably, PEMP may represent a crucial form of cell interaction involved in the association of hematolymphoid cells with their microenvironments. Symbiotic complexes of mouse lymphoid leukemias may be a promising in vitro model for analysis of such a cell interaction.

In the present paper, the dynamic morphology of the formation of symbiotic complexes is studied by means of SEM and microcinematography. We gave particular attention to the mechanism of the leukemia cells' entry into and exit from the microenvironment formed by TER. We showed that the association of leukemia cells with TER was based on active locomotion of the leukemia cells, and the integrity of the cytoskeleton of both leukemia cells and TER was essentially required for PEMP.

MATERIALS AND METHODS

Tissue culture.—Symbiotic cell lines were established from spontaneous thymic leukemias in AKR/Ms mice as described previously (*4*). The leukemic thymus was mechanically disrupted between two sheets of a frosted glass slide, vigorously pipetted, and allowed to stand for a few minutes. After the free leukemia cells were removed, tissue fragments were explanted in a culture flask. After 1–2 weeks, leukemia cells started to grow and were associated with the outgrowth of the glass-adherent TER-like cells from the explants. In earlier stages of such cultures, leukemia cells depended on the adherent cells for their in vitro survival and growth and PEMP was consistently observed. In this paper, we used the AKRL-16 cell line except when otherwise noted because of its stable growth behavior and high efficiency in PEMP.

ABBREVIATIONS USED: DMEM=Dulbecco's modified Eagle's minimum essential medium; DMSO=dimethyl sulfoxide; FCS=fetal calf serum; MEM=minimum essential medium; PBS=phosphate-buffered saline; PEMP=pseudoemperipolesis; %PEMP(≥1)=percentage of A17A cells holding one leukemia cell or more under their cytoplasm; %PEMP(≥5)=percentage of A17A cells holding five leukemia cells or more under their cytoplasm; SEM=scanning electron microscopy; TER=thymic epithelial reticular cell(s); TPA=12-*O*-tetradecanoylphorbol 13-acetate.

[8] We thank Dr. M. Matsuyama for critical reading of the manuscript and Mrs. Y. Oguro and Mr. S. Nakamura for excellent technical assistance.

The medium was the high-glucose version of DMEM (GIBCO, Grand Island, N.Y.) with 10% unheated FCS. One liter of DMEM was also supplemented with 60 mg kanamycin sulfate, 110 mg sodium pyruvate, 860 mg MEM amino acids–vitamins (Nissui Seiyaku Co. Ltd., Tokyo, Japan), and 10 ml of a 100 times concentrated MEM nonessential amino acid solution (GIBCO). Cultures were kept in a CO_2 incubator with 6% CO_2 and 94% fully humidified air. Medium was changed twice a week.

Isolation of intrinsic adherent cells from symbiotic stock culture.—The method for the isolation of thymic nurse cells from normal thymus described by Wekerle et al. (*3*) was used with modifications. The symbiotic stock culture was washed with three changes of Ca^{2+}-free and Mg^{2+}-free Dulbecco's PBS and digested with 5 ml of 0.01 *M* EDTA–0.25% trypsin in Dulbecco's PBS for 10 minutes at 37°C. After two washes in serum-free DMEM, the digest in 1 ml was overlaid on 4 ml FCS in a 10-ml culture tube and kept standing at room temperature for 15 minutes. Subsequently, the top one-third layer containing mainly leukemia cells was aspirated off, and the bottom layer enriched with adherent cells was spun down. After two washes, the cells in 5 ml DMEM with 2% FCS were propagated in a TD-40 glass flask with a surface area of approximately 40 cm^2. Two hours later, nonadherent cells were removed by being repeatedly washed with Dulbecco's PBS, and the adherent cells were fed with DMEM plus 10% FCS and kept in culture. The entire procedure was repeated daily until all leukemia cells were removed. In this work, a colonial clone A17A isolated from symbiotic AKRL-17 leukemia was used throughout.

Assay of PEMP.—The degree of PEMP was measured as in (*5, 7*) with modification. A17A cells, 5×10^4 in 3 ml of medium, were plated in a 60-mm plastic petri dish. One day later the monolayer was washed twice with Dulbecco's PBS, and 3×10^6 washed leukemia cells in 4 ml of DMEM plus 1% FCS were overlaid. After 6 hours of incubation at 37°C, free leukemia cells were washed out by three changes of Dulbecco's PBS, and the monolayer was fixed with methanol and stained with Giemsa. The %PEMP(≥1) and %PEMP(≥5) were determined by the examination of approximately 1,000 A17A cells under a microscope. Although %PEMP(≥5) roughly paralleled %PEMP(≥1), %PEMP(≥5) was a more sensitive measure for the effects of the various inhibitors.

Chemicals.—Cytochalasin B and cytochalasin A (Aldrich Chemical Co., Milwaukee, Wis.) were dissolved at 1 mg/ml in DMSO, colchicine (Wako Pure Chemical Co., Osaka, Japan) was dissolved at 10 m*M* in culture medium, and TPA (Consolidated Midland Corp., Brewster, N.Y.) was dissolved at 100 µg/ml in absolute ethanol. All stock solutions were stored frozen at −20°C and diluted in culture medium immediately before use.

Evaluation of inhibitory effects on PEMP.—Leukemia cells, 3×10^6 in 4 ml of the medium containing a test chemical at an appropriate final concentration, were seeded on top of A17A cells. After 6 hours of incubation, the %PEMP(≥1) and %PEMP(≥5) were measured as above. Inhibition of the preformed PEMP was studied by incubation of the leukemia cells on top of the A17A cells for 6 hours without an inhibitor and subsequently by replacement of the medium with 4 ml fresh medium with or without the inhibitor. The %PEMP(≥1) and %PEMP(≥5) were determined 5, 10, 20, 30, 45, and 60 minutes after addition of the inhibitor. To determine the target of action of the chemicals, we preincubated either leukemia or adherent cells with the chemicals and we examined the capacity of PEMP as follows: Leukemia cells, 8×10^6, were incubated for 1 hour at 37°C in 5 ml of the medium with or without an inhibitor. Also similarly incubated were 5×10^4 A17A cells plated 1 day earlier in a 60-mm plastic petri dish. After the treatment adherent cells and leukemia cells were washed carefully by three changes of fresh medium, and PEMP was determined in combination with untreated cells. The viability of the cells was determined by the trypan blue dye exclusion test.

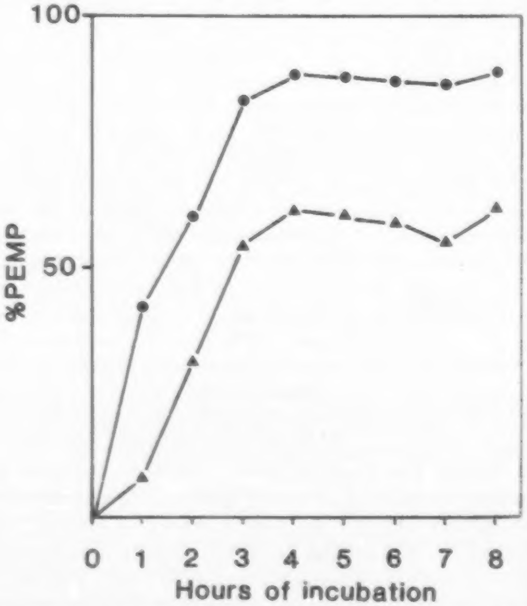
Microcinematography.—A Nikon inverted phase-contrast microscope with a built-in incubator maintained at 37°C was used as optical equipment. With the use of a Borex H16 camera with a Nikon CFMA cine-autotimer, photographs were taken on 16-mm Fujicolor RT500 cinefilm. Intervals of exposures (2, 4, 15, or 30 sec) were selected depending on the duration of observation.

Electron microscopy.—SEM was done as in (*4, 5*).

RESULTS

PEMP of Symbiotic Leukemia Cells

As shown previously (*4, 5*), in vitro survival and growth of leukemia cells of symbiotic cell lines in earlier passage generations required close association with glass-adherent stromal cells, and the complexes containing both types of cells formed a germinative layer. Localization of the leukemia cells under adherent cells, i.e., PEMP, was a prevalent morphologic feature in this layer (fig. 1). The degree of PEMP could be measured by the %PEMP(≥1) and the



TEXT-FIGURE 1.—Kinetics of PEMP. AKRL-16 leukemia cells under A17A adherent cells. ●: %PEMP(≥1); ▲: %PEMP(≥5).

%PEMP(≥5). As a source of the adherent cells for PEMP assay, the cloned cell line A17A was used throughout. It was isolated from a symbiotic stock of AKRL-17 leukemia and had a TER-like morphology (fig. 2). Text-figure 1 depicts the time course of PEMP of AKRL-16 leukemia cells under A17A cells. Approximately 5-6 hours after the cells were plated, a plateau was attained and the average number of leukemia cells under an A17A cell was maximum (data not shown). Leukemia cells from all of eight different symbiotic cell lines were capable of PEMP with A17A cells but at varying degrees (table 1). Thereafter, a combination of AKRL-16 leukemia cells and A17A cells was used, since it gave highly consistent results in the PEMP assay.

Microcinematographic Observation

To determine whether PEMP occurred by active movement of the leukemia cells or by passive entrapment by the adherent cells, we observed the process of PEMP by time-lapse cinematography. After being plated on a sparse culture of A17A cells, leukemia cells exhibited active locomotion on the substrate or on A17A cells. The locomotion was nondirectional, and the association of leukemia cells with A17A cells appeared to occur by chance. Some leukemia cells anchored on the surface of A17A cells by their uropods and frequently twirled on one spot. Others "crawled" around the periphery of A17A cells, occasionally touching the periphery with pseudopods as if investigating the cell margin. In contrast, A17A cells were relatively stationary with the exception of slower ruffling of lamellipods.

Invasion of leukemia cells under A17A cells usually took place without any predictable changes in motility of both cells. In figures 3A-3E, three leukemia cells were seen to move in under an A17A cell. The leukemia cell in contact with the A17A cell at the cell margin (fig. 3A) rapidly protruded pseudopods and extruded them under the A17A cell (figs. 3B-3D). Figure 4 is an SEM picture showing a leukemia cell in the process of PEMP. The portion of the leukemia cell cytoplasm already under the A17A cell could be seen through the thin cytoplasmic membrane. The gateway of entry appeared to be narrow, since the leukemia cells moving in were considerably constricted at the site (figs. 3B, 3C). But once the leukemia cells were under the adherent cells, the motility of the leukemia cells looked as unrestricted as that seen when the leukemia cells were outside the A17A cells. During the entry of the leukemia cells under an A17A cell, the A17A cell remained almost unmoved. The time required for the entry varied (5-15 min on the average). Under adherent cells, leukemia cells twirled on the spot or "crawled" around. Occasionally, a group of cells became involved in a sudden rotatory movement. When an A17A cell with many leukemia cells in PEMP divided, the leukemia cells were expelled as the dividing A17A cell rounded up. However, the leukemia cells were somehow bound to the A17A cell, since they were rapidly accommodated again under the daughter A17A cells after division. Leukemia cells stayed under an A17A cell for varying periods ranging from 15 minutes to over 6 hours, and the fate of each cell was apparently determined individually. Exit of the leukemia cells occurred as an almost exact reverse of their entry.

TABLE 1.—*PEMP of various symbiotic leukemia cells under A17A cells*

Cell line	%PEMP(≥1)[a]	%PEMP(≥5)[a]
AKRL-16	56.3±2.5	26.1±2.0
AKRL-17	48.6±3.2	25.8±1.1
AKRL-25	56.1±1.8	19.2±2.7
AKRL-26	46.3±0.6	17.2±1.9
AKRL-36	81.3±4.2	40.0±2.3
AKRL-38	62.1±1.8	23.3±0.8
AKRL-46	28.9±2.0	8.6±0.6
AKRL-47	27.9±1.7	7.2±1.1

[a] Results are means ± standard deviations. Assays were done in triplicate.

Effect of Cytochalasins

Cytochalasins (microfilament-disrupting agents) were found to be potent inhibitors of PEMP. In the presence of 2.5 μg or more cytochalasin B/ml, PEMP did not occur and the minimum effective concentration was 0.04 μg/ml (text-fig. 2A). The solvent DMSO was inhibitory to PEMP at 1%, but it did not affect PEMP below 0.5% (text-fig. 2A). The inhibitory effect of cytochalasin A was approximately five times as strong as that of cytochalasin B (data not shown).

To determine whether the leukemia cells or adherent cells were the target of cytochalasins, we treated the cells with either cytochalasin A or cytochalasin B for 1 hour, washed them extensively, and examined them for the capacity of PEMP by combining the treated and untreated cells. As shown in table 2, pretreatment of both cells with cytochalasin A abolished PEMP. The leukemia cells were more susceptible than were the A17A cells, since 50% specific inhibition in %PEMP(≥1) was observed in leukemia cells at 0.25 μg/ml, whereas in A17A cells it was observed at 2 μg/ml. Similar treatment with 2.5 μg cytochalasin B/ml was without effect inasmuch as its action was reversible (*8*). Microcinematography showed that addition of 2.5 μg cytochalasin/ml almost instantly inhibited the locomotion of leukemia cells, caused cessation of the crawling movement under the A17A cells, and caused rapid retraction of the cytoplasm of the A17A cell. Since cytochalasin B did not affect the adherence of A17A cells to the substrate, the retraction of the cytoplasmic sector between adherence sites produced a bizarre stellate morphology in A17A cells. When cytochalasin B was added to the A17A cells with many leukemia cells in PEMP, the leukemia cells were quickly liberated (text-fig. 2B)—a result of the rapid retraction of the covering A17A cell cytoplasm as revealed by microcinematography and SEM (figs. 5, 6). That the effects of cytochalasins on PEMP were due to sublethal cell damage is unlikely, since the viability of both cells after 6 hours of incubation with 2 μg cytochalasin A/ml or 2.5 μg cytochalasin B/ml remained over 85%, as judged by the trypan blue dye exclusion test. Therefore, the effects of cytochalasins on PEMP seemed to be dual: inhibition of the active locomotion of leukemia cells and contraction of the adherent cell cytoplasm.

Effect of Colchicine

Colchicine (a representative microtubule poison of the

Vinca alkaloids) was also a strong inhibitor of PEMP. It suppressed PEMP at 10^{-4} m*M* or at higher concentrations (text-fig. 3A). Microcinematography showed that the locomotion of the leukemia cells was inhibited and the A17A cell cytoplasm was contracted immediately after addition of colchicine. Rapid release of the leukemia cells was observed from preformed PEMP complexes after addition of colchicine, depending on its concentration (text-fig. 3B). This rapid release was the result of the contraction of the covering A17A cell cytoplasm as shown by microcinematography as well as by SEM (Figs. 6C, 6D). When either leukemia cells or A17A cells were pretreated with colchicine for 1 hour and washed and their capacity for PEMP was examined, there was a moderate, but definitive, inhibition in PEMP by either treatment (table 2). The effect was more visible in %PEMP(≥5) than in %PEMP(≥1). The leukemia cells were more susceptible to this treatment than were A17A cells. Both leukemia cells and A17A cells remained over 85% viable after 6 hours of incubation in 10^{-1} m*M* colchicine.

Effect of TPA

Previously, we learned that tumor-promoting phorbol esters are inhibitory to PEMP (*7*). This finding was con-

firmed when a combination of the AKRL-16 leukemia cells and A17A cells was studied (text-fig. 4A). Addition of TPA to preformed PEMP complexes released the leukemia cells in a dose-dependent way (text-fig. 4B). Unlike the immediate action of cytochalasins and colchicine (text-figs. 2B, 3B), there was an approximately 10-minute delay before any measurable effect of TPA on PEMP became manifest. Microcinematography and SEM revealed that the effects of TPA were also to inhibit locomotion of the leukemia cells and to contract the A17A cell cytoplasm. The release of leukemia cells from complexes was caused by retraction of the A17A cell cytoplasm (figs. 6E, 6F). TPA was not toxic to either leukemia cells or A17A cells by 6 hours of incubation at 40 ng/ml.

DISCUSSION

Observation of the dynamic morphology of symbiotic complex formation by murine leukemias revealed that association of leukemia cells with their microenvironments in the form of PEMP was a consequence of the leukemia cells' actively moving in under the adherent cells. Apparently, this movement occurred as nondirectional motility of leukemia cells rather than as adherent cell-directed chemotaxis.

In contrast, the adherent cells seemed to play a rather passive role in PEMP. Entry of the leukemia cells into a space under the adherent cells was usually observed to start from the margin of the adherent cell. The currently available method with the use of cultured symbiotic leukemias allows observation of the cell interaction in only two dimensions. In vivo, however, such complexes may well be composed of a three-dimensional network of interwoven thymic epithelium forming a basket-like packet filled with normal or leukemic lymphocytes and other elements. Clark (*9*) has proposed such a packet as a unit structure of normal thymus. Immigration of lymphoid precursors of extrinsic origin into the thymic rudiment was observed by microcinematography in a thymus organ culture of a 4-day-old larvae of *Xenopus laevis* (*10*). In contrast to the organ culture method, our symbiotic culture has the advantage of allowing more direct observation of cell-to-cell interaction. It also allows for quantitation of the phenomenon.

The present study revealed that the integrity of the cytoskeletal system was essentially required for the association of leukemia cells with their microenvironments. Both cytochalasins and colchicine strongly inhibited PEMP at concentrations without toxic injury to either leukemia cells or A17A cells. The action of both compounds was probably dual. The primary target of these compounds was the motile apparatus of the leukemia cells, inasmuch as the compounds paralyzed the locomotion of leukemia cells and thus prevented the occurrence of PEMP. However, these compounds caused rapid contraction of the A17A cell cytoplasm, so that the affected cells were unable to hold leukemia cells under them. The release of the leukemia cells immediately after addition of the chemicals to preformed complexes was a result of contraction of the A17A cells, as visualized in microcinematography and SEM. The effect of pretreatment of cells with these chemicals was less evident in the adherent cells than in the leukemia cells. The pretreated adherent cells could accept leukemia cells to a lesser or greater degree despite marked deformity and contraction of the cytoplasm. Such a difference in susceptibility to the pretreatment seemed partly due to the passive role of the adherent cells in complex formation. Inasmuch as the selective actions of cytochalasins on microfilaments (*11*) and colchicine on microtubules (*12*) have been well established, both cytoskeletal systems are involved in PEMP. However, details of their mechanisms of action remain unclear.

Previously, we reported that tumor-promoting phorbol esters stimulate in vitro growth of many microenvironment-dependent leukemias and at the same time inhibit PEMP (*7*). The present study confirmed and extended the findings with regard to the inhibition of PEMP. Microcinematography as well as SEM revealed that TPA inhibited the locomotion of leukemia cells and also caused contraction of adherent cells at nontoxic concentrations. We concluded previously (*7*) that the primary action of TPA was on the leukemia cells, since the pretreatment of the leukemia cells prevented PEMP but pretreatment of the adherent cells had a negligible effect. In light of the present study, however, the action of TPA seemed to be dual also. The action of TPA was apparently similar to the actions of cytochalasins and colchicine. TPA has been proved to disorganize the cytoskeletal system of the cells and to modulate their phenotype, mimicking the phenotype of transformed cells (*13*). TPA-induced inhibition of PEMP, therefore, may well be related to the action of TPA on the cytoskeletal system. However, it is not currently known if TPA acts directly on the cytoskeleton or on another motile apparatus or if TPA somehow secondarily affects the cytoskeleton. Unlike the almost immediate action of cytochalasin B or colchicine, an approximately 10-minute delay was noted by us before the effects of TPA on PEMP became visible. Rifkin et al. (*13*) reported that the action of TPA on the cytoskeleton requires synthesis of RNA and protein, since actinomycin D and cycloheximide abolish the effect of TPA. The observed delay in our experiment may represent the time required for intracellular events ultimately leading to modulation of the cytoskeleton.

Our previous study indicates that an indispensable step of leukemogenesis is that developing mouse thymic leukemias must form symbiotic complexes with thymic microenvironments (*4, 7*). Since growth of microenvironment-dependent leukemias requires close cell association with TER, any interference of the interaction may well cure or prevent the disease. The present study clearly showed that the integrity of the cytoskeleton was essential for the complex formation. Therefore, for this hypothetical approach to chemotherapy, chemicals affecting the cytoskeleton would be of choice. In a parallel study, we found that chemotherapeutic agents of *Vinca* alkaloids having a high affinity for microtubules strongly inhibited PEMP at concentrations without direct cytotoxicity (Hiai H, Fukushima M, Oguro Y, Nishizuka Y: Manuscript in preparation). Selective clinical indication of these agents for lymphoid malignancies might be explained at least in part by their action on the cell interaction proper to the lymphoid system rather than toxicity on growing cells. For further exploration of this possibility, the nature of the interaction between normal or neoplastic hematolymphoid cells and their microenvironments has to be elucidated. Symbiotic culture of mouse leukemias, therefore, will provide a useful in vitro model for the study of chemotherapy of lymphoid leukemias in this novel approach.

A High-Tumor-Incidence Subline of the D1 Mouse Mammary Hyperplastic Outgrowth Line: Effect of Carcinogens [1,2,3]

Rhoda L. Ashley,[4,5] **Robert D. Cardiff,**[4,6] **Terry S. Pratt,**[4] *and* **Leslie J. Faulkin**[7,8]

ABSTRACT—Mammary tumorigenesis in some mouse strains is characterized by the appearance of a preneoplastic lesion, the hyperplastic alveolar nodule (HAN). The biology of the HAN has been characterized primarily through the study of stable outgrowth lines of serially transplanted HAN. One outgrowth line, DI, which was developed and carried in female BALB/c mice, has been described as a low-tumor-incidence line that does not express murine mammary tumor virus (MuMTV) and is susceptible to hormonal, chemical, and viral carcinogens. In this report, a high-tumor-incidence subline of DI, DI/UCD, is described. Although DI/UCD, like DI, is susceptible to the chemical carcinogen 7,12-dimethylbenz[a]anthracene, an increase in tumor incidence was not observed when DI/UCD outgrowth was exposed to hormones by means of pituitary isografts. Unlike DI, DI/UCD is refractory to the carcinogenic action of MuMTV. Both DI and the DI/UCD subline contained the endogenous MuMTV provirus but did not contain exogenous MuMTV provirus sequences. MuMTV antigen was not detected in DI/UCD outgrowths or tumors. RNA hybridizable to MuMTV complementary DNA was detected in some DI/UCD outgrowths and tumors but did not appear to correlate with tumorigenesis.—JNCI 1982; 69:639–645.

Mammary tumorigenesis in certain mouse strains is a multistage process characterized by an intermediate, biologically distinct, proliferative lesion or HAN (*1*). The cells of the HAN are at higher risk for tumor development than are those of the surrounding mammary parenchyma (*2, 3*). Therefore, HAN have been termed "preneoplastic" (*4*). Unlike normal lactating mammary epithelium, the HAN does not require lactogenic hormone stimulation for maintenance and is able to survive indefinite serial transplantation in the gland-free mammary fat pad of syngeneic hosts (*3, 5*). In vivo transplantation techniques have provided a means for studying the biology of premalignant neoplasia (*1, 6–8*). Stable outgrowth lines that have been developed from individual HAN are particularly useful for identification and analysis of factors that affect the emergence of tumors from preneoplastic lesions.

One of these lines, Dl, was developed from a BALB/c HAN that arose after hormonal stimulation of the host (*9*). Outgrowths from early transplant generations of this line rarely developed tumors but were shown to be highly susceptible to the action of various carcinogens, as evidenced by increased tumor incidence and reduced latent periods for tumor development. Prolonged hormonal stimulation and chemical carcinogens, such as DMBA and the MuMTV, have been shown to increase tumor incidence in Dl tissue (*9, 10*).

In our recent work with Dl we used outgrowth tissue from the 40th to the 45th transplant generation. In these later generations, the Dl differs from early transplant generations in its increased tumor incidence and in its lowered response to the tumorigenic effects of MuMTV infection. The tumor incidence of Dl in the BALB/c host is greater than 70% at 9 months (*6*), as compared to the less than 30% incidence at 12 months reported by other investigators (*10, 11*). In contrast to previous studies with MuMTV, repeated studies in this laboratory demonstrated that the mean latent period for tumors from Dl outgrowths in the BALB/cfC3H host is as much as 3 months longer than that observed in Dl outgrowths in the BALB/c host (*6*). Because of these changes, we consider the later generations of Dl in our laboratory as a distinct subline of Dl and call it "Dl/UCD."

This report of our continuing studies on Dl/UCD describes the kinetics of tumorigenesis of Dl/UCD outgrowth and the effects of MuMTV and other tumor-inducing agents on tumor incidence and latency. Dl/UCD outgrowths and tumors from carcinogen-treated and untreated animals were also analyzed for MuMTV antigen and RNA to determine whether overt changes in the virology of Dl were associated with the observed biologic changes.

MATERIALS AND METHODS

Transplantation.—Female BALB/c mice (3 wk old) were obtained from Simenson Laboratories, Gilroy, Calif. Mice were anesthetized, and the inguinal mammary fat pads were surgically exposed and cleared of all epithelial elements, as described in (*2*). Transplants of BALB/c Dl outgrowth were made into the cleared fat pads. The Dl outgrowth was originally obtained in transplant generation 40 from the Cancer Research Laboratory, University of California, Berkeley, Calif. Transplant recipients were held 5 per cage, as virgins, under controlled conditions of temperature and light. Water and food were provided ad libitum.

ABBREVIATIONS USED: cDNA=complementary DNA; df=degrees of freedom; DMBA=7,12-dimethylbenz[*a*]anthracene; HAN=hyperplastic alveolar nodule; IP=immunoperoxidase; MuMTV=murine mammary tumor virus; SDS=sodium dodecyl sulfate.

[8] We are grateful to Mr. D. J. Mitchell and Ms. J. Walls (Department of Veterinary Anatomy, School of Veterinary Medicine) and to Ms. J. K. Lund and Dr. T. G. Fanning (Department of Pathology, School of Medicine) for their technical assistance.

By gastric intubation, 1 group of Dl recipients (Dl generation 42) received 0.5 mg DMBA (Sigma Chemical Co., St. Louis, Mo.) at 4 weeks and again at 6 weeks post transplantation. This experiment was repeated with recipients of Dl from generation 43. The dose of DMBA remained at 0.5 mg but was administered at 12 and 14 weeks post transplantation. Another group of transplant recipients (Dl generations 42 and 43) received two or three male pituitary isografts by subrenal capsule implantation at the time of transplantation of the Dl/UCD. Finally, a group of mice (recipients of Dl generation 43 or 44) were held as untreated controls.

Animals from all groups were checked weekly for tumor development in transplant sites and in host mammary glands. One tumor was detected in a host gland site in a DMBA-treated host and was identified as a sarcoma. No mammary tumors were observed in host tissues during the course of the study. Autopsies were performed on tumor bearers to confirm the presence of tumors in the transplant sites and to confirm growth of contralateral transplants. At the termination of each experiment, all animals were killed and autopsies were performed. Only those transplants that had filled at least 50% of the fat pad were considered in the incidence calculations. Hormonal stimulation was confirmed at autopsy in those animals that received pituitary isografts by the noting of secretion in the host mammary glands and transplants. All tumor bearers in these groups showed evidence of hormonal stimulation. The low number (<1%) of those mice that were not obviously stimulated did not develop tumors and were not considered in calculations of the incidence figures.

At 12 weeks post transplantation, 30–40 mice from each group were killed, and hyperplastic outgrowths, tumors, host mammary glands, livers, kidneys, and spleens were collected. Portions of these tissues were taken for IP staining, and the remaining tissue was held at −70°C. Those animals that were killed at 12 weeks post transplantation were not considered in compiling tumor incidence data.

Tumors were collected when they reached approximately 1–2 g. Host mammary glands, livers, kidneys, and spleens from tumor bearers were collected and frozen. Most animals at the time they were killed for large tumors had smaller tumors in the contralateral transplant. Portions of all tumors were fixed for PAP staining and the remaining tissue was held at −70°C.

IP staining.—To test for the presence of MuMTV antigen, we used a modification of the immunocytochemical methods of St. George et al. (*12*) and Vacquier and Cardiff (*13*), as described in detail in (*6*).

RNA extraction.—The RNA was extracted as previously described (*6, 8*). Frozen tissue was weighed and, while frozen, 2–5 g was minced before suspension in 10 vol/g TE buffer.[9] The slurry was homogenized and adjusted to 0.1 *M* NaCl and 0.5% SDS. Nucleic acids were extracted twice with phenol and once with phenol–chloroform–isoamyl alcohol (50:50:1). The aqueous phase was adjusted to 0.3 *M* NaCl, and 1 volume of cold absolute ethanol was added. After the DNA was spooled onto glass rods, a second volume of ethanol was added, and RNA was precipitated twice from ethanol at −20°C. The RNA was treated with DNase as described in (*6*), extracted with phenol, and stored at −70°C in TE buffer[9] (pH 7.4). MuMTV RNA was extracted from virions purified from tissue culture fluid as previously described (*6, 8, 14*).

[^{32}P]cDNA.—Labeled DNA complementary to MuMTV RNA was synthesized in a 100-μl reaction mixture containing 200 m*M* each of dTTP, dCTP, and dGTP; 50 m*M* Tris-HCl (pH 8.1); 75 m*M* KCl; 10 m*M* $MgCl_2$; 2 m*M* dithiothreitol; 25 μg actinomycin D/ml; 100 μCi α-[^{32}P]dATP (2,000–3,000 Ci/mmol; Amersham Corp., Arlington Heights, Ill.); 1.0 μg MuMTV RNA; 1.2 μg calf thymus DNA primers (*15*); and 100 U avian myeloblastosis virus RNA-dependent DNA polymerase provided by Dr. J. Beard (Life Sciences, Inc., St. Petersburg, Fla., through the Research Resources, Biological Carcinogenesis Branch, National Cancer Institute). After 30 minutes at 37°C, the reaction was stopped by the addition of EDTA, SDS, an NaOH to final concentrations of 0.05 *M*, 0.5%, and 0.3 *M*, respectively, and the mixture was incubated at 65°C for 3-4 hours to hydrolyze the RNA. The mixture was neutralized and then was passed over a Sephadex G-50 column. The excluded fractions were pooled, were precipitated in ethanol, and then were suspended in 10 m*M* Tris–HCl (pH 8.0) and 1 m*M* EDTA. The final cDNA had a specific activity of 2×10^4 cpm/pg (*8*). The probe was characterized as described below.

Characterization of the [^{32}P]cDNA probe.—Hybridization levels of the [^{32}P]cDNA in reactions containing MuLV RNA or yeast RNA were minimal (<5%), indicating specificity for MuMTV. The cDNA hybridized to template RNA to a 65% maximum and at a $C_rt_{1/2}$[10] of 6×10^{-2} mol×sec×liter^{-1} (*8*). To test the extent to which the probe represented the MuMTV genome, we used aliquots of the [^{32}P]cDNA in the Southern blot technique (*16*) to detect Pst I endonuclease fragments from DNA containing the MuMTV endogenous and exogenous proviruses. The fragment pattern reported by Cohen et al. (*17*) was consistently reproduced with this probe (*6, 14*). These results indicate that all of the 35S genome was represented in our probe. However, since the probe was not reannealed back to 35S RNA before use, some degree of over-representation of subgenome portions of the template RNA was possible. To directly test the extent of subgenome over-representation in the probe, we used the cDNA to protect ^{125}I-labeled MuMTV 35S RNA from RNase A degradation. The probe protected 85% of the RNA at a ratio of 10:1, indicating a low level of sequences present in excess of other sequences.

RNA:[^{32}P]cDNA liquid hybridization.—The annealing mixture contained 0.3 *M* NaCl, 25 m*M* Tris-HCl (pH 7.4), 2 m*M* EDTA, 30,000 cpm [^{32}P]cDNA, and 5–7 mg RNA/ml in a total volume of 150 μl (750–1,050 μg RNA) (*8*). Nucleic acids were boiled for 1 minute and quickly chilled on ice before addition of the remaining components of the reaction mixture. Hybridizations were conducted up to 96 hours at 68°C; C_rt[10] values were varied by time (*8*). Periodically, 10-

---

[9] 10 m*M* Tris (pH 9.2) and 1 m*M* EDTA.

[10] C_rt=product of concentration and time (mol×sec×l^{-1}); $C_rt_{1/2}$=50% of the product of RNA concentration and time.

μl aliquots of the reaction mixture were removed and placed into 1.1 ml ice-cold, freshly-made SI buffer.[11] Two 0.5-ml aliquots from this mixture were then removed, and 12 μl SI nuclease (5 μg; Miles Laboratories, Inc., Elkhart, Ind.) was added to 1 aliquot. All samples were then incubated for 2 hours at 50°C. Nucleic acids were precipitated with 2.0 ml cold 10% trichloroacetic acid in the presence of yeast RNA and were counted in phase combining system scintillation fluid.

RESULTS

Tumor Incidence in D1/UCD Outgrowth

Tumor incidence in postgeneration 40 D1 outgrowth (D1/UCD) was greater than 70% by 9 months post transplantation. When D1/UCD was exposed to MuMTV by transplantation into BALB/cfC3H animals, tumor incidence at 9 months was approximately 30%; after 12 months, 70% tumor incidence was attained in this group (*6*). Thus the major effect of MuMTV on D1/UCD outgrowth was to substantially prolong the mean latent period of tumorigenic development.

The effect of other tumor-inducing regimens, including treatment with DMBA and introduction of pituitary isografts, was examined in this study. The experiments were designed in such a way that periodic samples of the hyperplastic outgrowth were taken from each group for virologic analysis. Because of these experimental manipulations and accidental loss of animals, the number of fat pads at risk of tumor development diminished with time. Therefore, to provide an accurate description of tumor development in D1/UCD outgrowths, we have expressed the data in three forms: 1) Tumor incidence was calculated at a given time post transplantation as the number of tumors per total viable transplants (table 1); 2) cumulative tumor incidence was determined by amending the total number of tumors at weekly intervals over the entire recorded period (text-fig. 1); and 3) age-specific incidence data (*18*) were also generated from the number of tumors arising in a given month relative to updated values for transplants at risk due to prior tumor development, experimental manipulation, or animal death (table 2; text-fig. 2).

When DMBA was given 4–6 weeks post transplantation, 71% of the D1/UCD transplants developed tumors by 14 weeks post transplantation. In contrast, 2.5% of the D1/UCD in untreated animals had developed tumors at that time. The experiment was repeated to generate data on the kinetics of tumor development after DMBA treatment. We chose the same dose of DMBA (0.5 mg) and administered it 12 and 14 weeks post transplantation. A rapid increase in tumors was observed in this second DMBA trial as reflected in the cumulative tumor incidence curve (text-fig. 1). The overall tumor incidence in this second group was 85% (table 1) at 29 weeks when all of the transplants at risk had developed tumors (table 2). This incidence compared with the 45% tumor incidence in D1/UCD from untreated controls (table 1), a significant difference by the chi-square test (df=1; *P*<0.001]. In contrast to the DMBA-treated animals, a significant number of D1/UCD transplants in untreated animals had not developed tumors when the experiment was terminated at 39 weeks (table 2; text-fig. 2).

TABLE 1.—*Tumor incidence in D1/UCD transplants[a] with carcinogen treatment*

Treatment	D1 generation	No. of tumors/No. of transplants	Percent tumors	Mean latent period, wk	Termination, wk
None	43	2/80	2.5	—	14
DMBA[b]	42	103/145	71.0	—	14
None	43	36/80	45.0	22.0	29
DMBA[c]	43	29/34	85.3	23.8	29
None	43	43/80	56.3	24.5	34
Hormones[d]	42	38/87	43.7	23.0	34

[a] D1/UCD was transplanted bilaterally into cleared mammary fat pads of BALB/c females, and each transplant site was examined weekly to determine the total No. of palpable tumors at the time of termination. Total transplants were determined by autopsy; transplants that failed to fill 50% of the host fat pads were not recorded. Palpated tumors were confirmed by autopsy.

[b] DMBA was administered 4 and 6 wk post transplantation.

[c] DMBA was administered at 12 and 14 wk post transplantation.

[d] Hormones were supplied by pituitary isografts as described in "Materials and Methods."

D1/UCD transplants in pituitary-treated animals initially developed tumors at the same rate as did D1/UCD transplants in untreated animals (text-fig. 1). The tumor incidence of the D1/UCD in treated animals, however, began to drop after the 6th month (table 2; text-fig. 2), whereas the tumor incidence continued to rise in the untreated animals (table 2; text-fig. 2). This resulted in a distinct plateau in the cumulative tumor incidence of D1/UCD in treated animals (text-fig. 1). When the experiment with pituitary-treated animals was terminated at 34 weeks, the overall incidence was 45%, as compared to 53% in the control group at the same time. This difference was not significant by the chi-square test (df=1; *P*=0.1). Further, the mean latent periods of 23.5 and 24 weeks were the same.

These data can be compared with the tumor incidence observed with the D1/UCD transplants in BALB/cfC3H animals (*6*) (text-figs. 1, 2). With MuMTV exposure, the mean latent period was prolonged, and the age-adjusted kinetics of tumor development were slower than those of the other groups. This distinctive kinetics profile of the D1/UCD tumors arising in BALB/cfC3H animals is consistent with the earlier observation that the biology of the D1/UCD in the BALB/cfC3H system is different from previous descriptions of the D1 line (*19*). These data suggest that while DMBA treatment increases the rate of tumor development in D1/UCD, other treatments, including hormone stimulation and exposure to MuMTV, do not increase either the incidence of tumors or the rate of tumor development.

Analysis of D1/UCD Tissues for MuMTV Antigen by IP

The D1/UCD outgrowth and D1/UCD tumors contained only the endogenous MuMTV proviruses (*6*). To determine

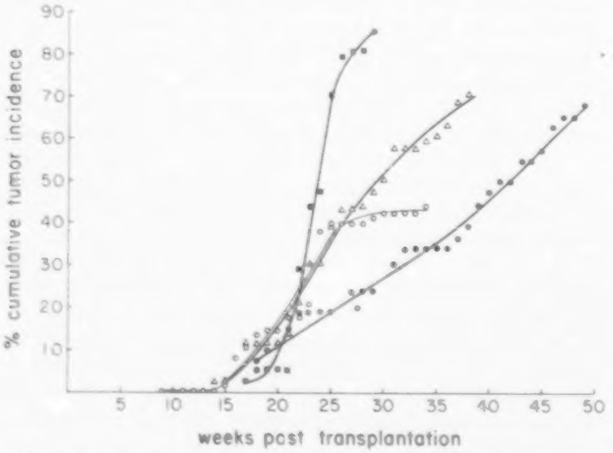
[a] D1/UCD outgrowth was transplanted into BALB/c mice that were treated with DMBA, received isografts of pituitary glands, or were untreated. D1/UCD outgrowth was also transplanted into BALB/cfC3H hosts for exposure to MuMTV. D1/UCD from generation 42 was transplanted into virus-positive animals, D1/UCD from generations 42 and 43 was exposed to hormone stimulation, D1/UCD from generation 43 was exposed to DMBA, and D1/UCD from generations 43 and 44 were untreated.

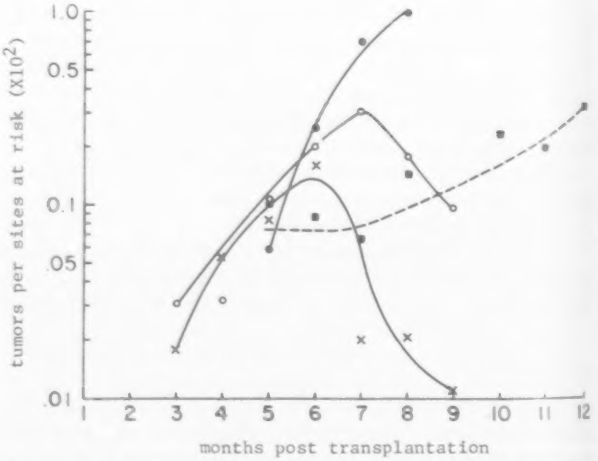
[b] No. of sites at risk was determined for each 1-mo period post transplantation by subtraction of those transplants that were no longer at risk due to tumor development or animal death.

[c] No. of tumors includes those tumors that became palpable within each 1-mo period and that were later confirmed by autopsy.

whether viral expression was a feature of the D1/UCD subline, we analyzed outgrowths and tumors for the presence of MuMTV antigen. We analyzed numerous samples of outgrowth and tumor from hormonally stimulated or DMBA-treated hosts with similar tissues from untreated D1/UCD hosts. MuMTV antigen could not be demonstrated in these tissues. However, antigen could be detected in D1/UCD outgrowths and tumors in BALB/cfC3H hosts (6). While the effect of sampling error cannot be ruled out, the results of this study indicate that expression of virus structural antigen in D1/UCD outgrowth or tumors from BALB/c hosts is, at best, a rare occurrence and is not induced in detectable levels by either treatment.



TEXT-FIGURE 1.—Cumulative tumor incidence in D1/UCD outgrowth. Total tumor incidence was calculated weekly from the initial transplants at risk. Both palpable tumors and transplants were confirmed by autopsy. D1/UCD tumors arose in DMBA-treated BALB/c hosts (■), hormone-stimulated BALB/c hosts (○), untreated BALB/c hosts (△); and MuMTV-infected BALB/cfC3H hosts (●).



TEXT-FIGURE 2.—Age-adjusted incidence of tumors in D1/UCD outgrowth. Incidence of palpable tumors was calculated every 4 wk post treatment from the total number of tumors arising in D1/UCD transplants during the period and the total number of transplants at risk during the period. D1/UCD tumors arose in DMBA-treated BALB/c hosts (●), BALB/c recipients of pituitary isografts (×), untreated BALB/c hosts (○), and MuMTV-infected BALB/cfC3H hosts (■). Tabulated data are presented in table 2.

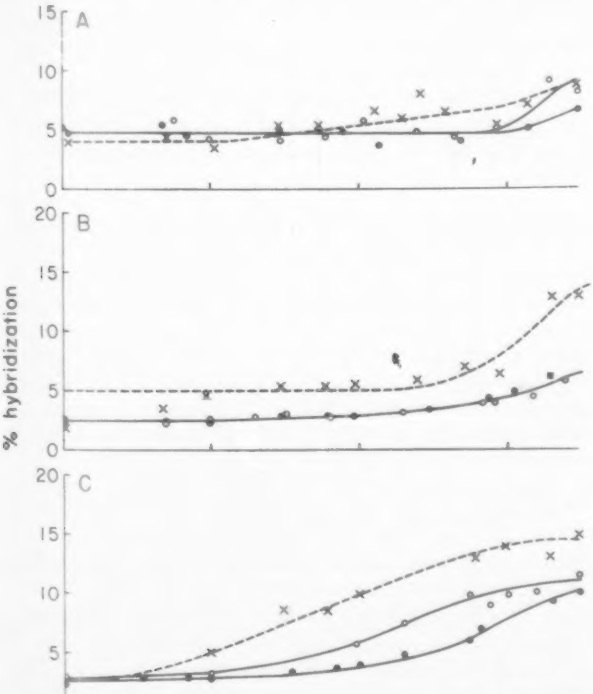
Analysis of D1/UCD Outgrowth RNA by Nucleic Acid Hybridization

D1/UCD tissues were also analyzed for MuMTV RNA. RNA from outgrowth obtained from hormone-stimulated animals had detectable levels of RNA that hybridized to our probe (text-fig. 3C). At high C_rt[10] values, D1/UCD outgrowth RNA from DMBA-treated animals hybridized to a greater extent (14%) than did that from pooled livers and host glands from this group (text-fig. 3B). Although these data are suggestive of MuMTV RNA expression, the low maximum hybridization level precludes quantitative comparisons with other tissues. Little or no hybridizable RNA was detected in any of the nontumor tissues tested from the BALB/c controls (text-fig. 3A).

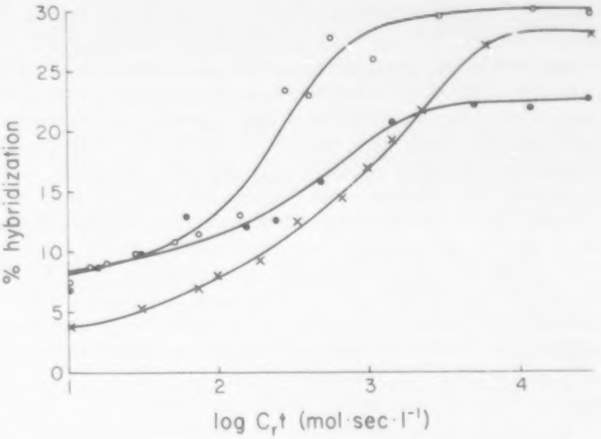
Analysis of D1/UCD Tumor RNA by Nucleic Acid Hybridization

RNA hybridizable to the MuMTV cDNA was detected in RNA from 2 of 8 D1/UCD tumors from untreated hosts (text-fig. 4). The RNA was tested from 6 randomly selected D1/UCD tumors occurring in the DMBA-treated hosts. In addition, 6 RNA preparations from D1/UCD tumors in the hormone group were tested. All 12 of these tumors contained RNA that hybridized to the MuMTV cDNA (text-fig. 4).

The maximum extent of hybridization differed according to the treatment of the D1/UCD hosts. RNA samples from DMBA-treated hosts hybridized to a higher maximum value (30%) than those from the hormone-treated and control groups (text-fig. 4). The level of hybridization was too low to reach a conclusion based on a quantitative comparison.



TEXT-FIGURE 3.—MuMTV RNA in D1/UCD outgrowth. D1/UCD outgrowths were pooled at 12 wk post transplantation or post treatment (DMBA-treated animals) from A) untreated BALB/c hosts, B) DMBA-treated BALB/c hosts, and C) BALB/c hosts with pituitary isografts. The RNA from the separate pools was hybridized to [^{32}P]cDNA as outlined in "Materials and Methods." D1/UCD outgrowths (×), host mammary gland (○), and liver (●) RNA preparations were tested from each group.



TEXT-FIGURE 4.—MuMTV RNA in D1/UCD tumors arising in untreated BALB/c hosts (●), DMBA-treated BALB/c hosts (○), or BALB/c hosts with pituitary isografts (×). RNA from individual tumors was hybridized to [^{32}P]cDNA as outlined in "Materials and Methods." Representative reactions from these tumors are presented.

DISCUSSION

The D1 subline has been widely used as a source of hyperplastic tissue of lower tumor incidence. We, like many investigators, began our studies with the assumption that D1 was a low-tumor-incidence outgrowth line. In the course of a long-term study of carcinogen effects on D1 outgrowth, we observed the increased tumor incidence reported here and elsewhere (*6*). Several investigators indicated to us that they had observed a comparable increase in the D1 tumor incidence (Medina D: Personal communication; Guzman, R: Personal communication).

All D1 lines may have become highly tumorigenic or maybe only the subline we obtained from the University of California, Berkeley, has a high tumor incidence. To facilitate comparison and maintain clarity in future reports, we have designated the outgrowth in our laboratory as "D1/UCD." As other laboratories publish their observations, the origin of the increased tumor incidence in D1/UCD may be resolved. In the meantime we report our observations on the increased, intrinsic, long-term tumor incidence in D1/UCD, and we further describe the effect of a chemical carcinogen and hormones on tumor incidence. We believe that in light of these data other investigators should carefully analyze their own D1 outgrowths before proceeding with experiments based on an assumption of low tumorigenicity.

The biologic characteristics of the D1/UCD subline differ in several respects from those of the parental D1 outgrowth line. The major difference is the increased tumor incidence of the D1/UCD line from generations 42 through 46, as compared to that reported for earlier generations of D1 (*10, 11*). Our analysis of D1/UCD indicated that the increased tumor incidence and decreased latent period were reproducible and could not be related to infection with exogenous MuMTV (*6*). The concern that the D1/UCD line was inadvertently infected with an exogenous virus was increased with the discovery that several BALB/c strains appeared in the restriction maps to have additional provirus DNA (*20*). However, numerous restriction maps of DNA from D1/UCD outgrowths and from tumors arising in D1/UCD outgrowths maintained in BALB/c mice contained only those MuMTV restriction fragments expected in the BALB/c genome (*6*). In addition, the D1/UCD outgrowth and tumors did not contain MuMTV antigens (*6*).

D1/UCD also differs from the parental D1 line in its relative lack of response to MuMTV as a tumor-inducing agent (*6*). In light of these pronounced differences, we examined the effect of other putative tumor-inducing agents on the new D1/UCD subline. The effects of chemical carcinogens and pituitary explants on the parental D1 line have been described (*1*). In D1, DMBA increased the tumor incidence from 4 to 67% and decreased the mean latent period from 404 to 207 days (*1*). Pituitary isografts had only marginal effects on tumor incidence, with an increase to 7% and a mean latent period of 371 days (*1*).

The DMBA treatment of hosts bearing D1/UCD resulted in accelerated tumor development. The effect of DMBA in terms of decreased mean latent period was clear with two different experimental designs: Treatment at 4 and 6 weeks resulted in rapid onset 8 weeks later, and treatment at 12 and 14 weeks resulted in an exponential rise in tumors 6–8 weeks later. Because of the differences in experimental design, direct comparisons between parental D1 and D1/UCD cannot be made. However, it is quite apparent that both are sensitive to chemical carcinogens.

The effects of pituitary isografts on the D1/UCD are difficult to interpret. The initial rise in tumor incidence was identical to that of the control curve, and the mean latent periods were similar. However, the appearance of new tumors suddenly slowed at 30 weeks. This phenomenon was reflected in both the cumulative tumor incidence and the age-specific incidence curves. We have no ready explanation for these observations, and inasmuch as the tumor incidence of the parental D1 was not analyzed in the same way, direct comparisons cannot be made. Clearly, tumor kinetics is a complex function that must be analyzed with the use of various parameters. Pituitary isografts resulted in a set of kinetics curves that differed from those generated by data from the control group.

As previously reported, transplantation of D1/UCD in BALB/cfC3H led to a prolonged latent period (*6*). The tumor kinetics curves for these transplants differ from those for the control group. The tumor kinetics for each experimental group were unique, and each differed from the kinetics predicted by the control group's curve. These studies helped delineate the biologic characteristics of the D1/UCD subline.

The second major issue explored in these studies was the possible association of detectable MuMTV antigen and RNA with tumorigenesis in the D1/UCD system. The D1 outgrowth line originated in BALB/c (*9*). BALB/c mice have endogenous MuMTV provirus DNA sequences (*21*). The MuMTV sequences appear to be highly repressed because MuMTV RNA is either very low or undetectable in mammary glands or tumors (*22–26*). Virion expression and antigen expression occasionally have been detected in spontaneous BALB/c tumors (*27–29*). These findings may be explained by undetected exogenous infection (*20*). Hormone induction of BALB/c tumors has been reported to be associated with some increase in virus RNA levels (*30*). However, DMBA-induced BALB/c tumors have had little or no detectable MuMTV RNA (*31–33*).

Tissue such as D1 outgrowth has been used to determine whether virus expression may occur in premalignant neoplasia. Several investigations have suggested that MuMTV RNA levels are higher in tumors than in outgrowths (*30, 33, 34*). We found no appreciable differences in the levels of virus RNA in BALB/cfC3H premalignant hyperplastic outgrowths and their tumors (*6*).

The analysis of D1/UCD RNA with MuMTV-specific cDNA probe revealed little or no increase in MuMTV RNA in the outgrowths as compared to that in BALB/c liver or lactating mammary gland RNA. D1/UCD RNA samples from DMBA and hormone-treated outgrowths hybridized to a greater extent to MuMTV cDNA. The difference, although slight, might suggest some expression of MuMTV RNA in the D1/UCD from treated animals. Viral antigens, however, were not detected in any of these tissues by IP methods.

The tumors from treated and untreated outgrowths were also analyzed for MuMTV RNA and antigens. Hybridizable RNA was detected in 2 of 8 D1/UCD tumors from the untreated group. In contrast, hybridizable RNA was detected in all of the D1/UCD tumors from the DMBA- and hormone-treated animals. While these findings are provocative, the percentage of putative MuMTV RNA detected was extremely low. Because of this low level of hybridization and the failure to detect MuMTV antigens in any tumor, virus expression probably is not correlated with increased tumor incidence in the D1/UCD subline.

The data reported in this study extend our previous observations concerning the biologic differences between D1/UCD outgrowth and the parental D1 line. These differences may provide an example of phenotypic drift resulting from selective pressure in serial passage. Although premalignant outgrowth lines are generally quite stable biologically, evidence has been presented for the heterogeneous nature of premalignant lesions and outgrowths (*8, 11, 35*). With repeated serial transplantation, subpopulations of cells with different biologic potential may dominate outgrowth population. Whether genetic alteration accounts for the phenotype changes seen in D1/UCD is uncertain. Studies using restriction endonuclease mapping suggest that the endogenous MuMTV provirus has remained stable in D1 and D1/UCD (*6, 21, 22*). Alteration of other genetic loci, however, cannot be ruled out as the possible basis for the differences between D1/UCD and D1.

The increased D1/UCD tumor incidence apparently is not due to introduction and maintenance of virus expression, as neither D1/UCD outgrowth nor most of the tumors studied from untreated hosts contained detectable MuMTV RNA or MuMTV antigens. The relative increase in D1/UCD tumor incidence with DMBA treatment was accompanied by detection of RNA that hybridized to the MuMTV cDNA in all of the D1/UCD tissues (outgrowths and tumors) tested. However, hybridizable RNA was also detected in all D1/UCD tissues after hormone treatment without an increase in tumor incidence. Further, the levels of RNA detected were extremely low, thereby limiting comparisons and conclusions. Even with these technical limitations the presence of hybridizable RNA in carcinogen-treated tissues could not be correlated with tumorigenesis. These conclusions serve to confirm and extend the observation that full MuMTV expression is not necessary for the maintenance of the malignant phenotype in BALB/c mice (*32*).

Antitumor Immunity Induced by Hybrid Murine Tumor Cells: Requirements for Optimal Immunization[1,2,3]

Craig S. McCune,[4] Robert W. O'Donnell,[4] Paul K. Horan,[5] Hollis S. Budd,[4] Janice L. Spennacchio,[4] Christy Chuang,[6] *and* Edgar C. Henshaw[4,7]

ABSTRACT—Hybrid tumor cells have been evaluated for their ability to induce specific antitumor immunity in inbred female C3H/He mice challenged with the syngeneic BA tumor. Hybrid cells were produced by fusion of BA cells with a BALB/c renal adenocarcinoma, which is hypoxanthine phosphoribosyl transferase-deficient and grows well in culture. *Corynebacterium parvum* was evaluated as an adjuvant for BA and hybrid cells. The BA tumor was shown to be poorly immunogenic, and four weekly injections of BA cells alone or *C. parvum* alone did not confer significant immunity. When BA cells and *C. parvum* were mixed, survival time was prolonged and most mice remained tumor-free. Hybrid cell lines derived from the BA tumor were produced in culture in unlimited quantities and were successfully used as immunogens. The addition of *C. parvum* to hybrids gave a significant incremental increase in survival when compared to the survival resulting from immunization by hybrids without adjuvant. When hybrids without adjuvant were used, several weekly injections were required for effective immunization. Irradiated and unirradiated hybrids were compared, and it was found that irradiation did not diminish hybrid immunogenicity. The potential problems and advantages of this concept of therapy are discussed.—JNCI 1982; 69:647–652.

Highly specific immune responses directed at tumor cells have been successfully produced in animals by injection of a suspension of viable irradiated syngeneic tumor cells mixed with an adjuvant (*1–4*). This approach evolved from an earlier observation by Zbar and Tanaka (*5*) that BCG injected into tumor nodules produced both local and regional destruction of tumor cells. The immune responses produced by tumor cell–adjuvant preparations have frequently rendered the animals tumor-free, and long-term immunologic memory has been demonstrated by a later rechallenge (*4*).

Successful clinical trials have been conducted on the basis of the methodology of these animal tumor models. Autologous tumor cells were used, and *Corynebacterium parvum* and BCG were employed as adjuvants. Regressions were noted in patients with malignant melanoma (*6*) and renal carcinoma (*7*). A major limitation to the tumor cell–adjuvant concept of treatment became apparent during the clinical trials: The quantity of autologous tumor cells obtained by tissue dissociation was often very small.

An alternative method to induce specific antitumor immunity is to substitute HTC for the syngeneic-autologous tumor cells. This possibility was entertained early in the development of cell fusion technology by Watkins and Chen (*8*) who successfully used hybrids to immunize mice against the Ehrlich ascites tumor. Several investigators have confirmed the potential of HTC as immunogens in a variety of animal tumor models (*9–15*). HTC have several potential advantages: First, they can be grown in culture to produce unlimited quantities. This attribute is acquired by selecting as one parent a permanent cell line which grows readily in culture. Second, there is empirical evidence that HTC express the TAA required for initiating antitumor immunity. Therefore, the essential antigens are also available in unlimited quantity. Third, the HTC surface membranes express foreign transplantation antigens. Because of the presentation of TAA in close proximity to foreign transplantation antigens, advantages have been postulated for the recognition process (*9, 13*). Fourth, several clones of HTC can be produced. Each clone represents a separate fusion with an individual tumor cell. This permits a new approach to the problem of tumor heterogeneity. Small subpopulations of antigenically distinct tumor cells can be represented on individual hybrid clones and amplified in culture.

In the experiments that we are now reporting, several potential requirements for optimal immunization with HTC have been evaluated: single versus repeated immunizations, irradiated versus unirradiated hybrids, injection with or without an adjuvant, and treatment with a single hybrid cell line versus a pool of three lines.

MATERIALS AND METHODS

Animals.—Inbred C3H/He female mice (Flow Laboratories Inc., Rockville, Md.) 6–10 weeks old were used.

Tumor lines.—The murine mammary adenocarcinoma C3H BA (M.A. Bioproducts, Walkersville, Md.) was origi-

[7] We thank Mrs. Helen Ochej and Dr. Irene Evans for their assistance at the Animal Tumor Research Facility, Dr. Thomas Shows for the RAG cell line, and the Burroughs Wellcome Co. for the *Corynebacterium parvum*.

nally a spontaneous tumor which has been passaged in syngeneic mice for several years. The RAG line was derived from a BALB/cf/Cd renal adenocarcinoma (*16*). A mutant subline which lacks the enzyme HPRT was obtained from Dr. Thomas Shows, Roswell Park Memorial Institute, Buffalo, N.Y. This cell line is maintained in culture in DMEM and 10% FBS and dies when exposed to HAT selective medium.

Enzymes.—Collagenase type I (Worthington Biochemical Corp., Freehold, N.J.), hyaluronidase type I (Sigma Chemical Co., St. Louis, Mo.), pronase B-grade (Calbiochem-Behring Corp., La Jolla, Calif.), and DNase type I bovine pancreas (Worthington Biochemical Corp.) were used for disaggregation of the tumor.

Chemicals and media.—PEG (J. T. Baker Chemical Co., Philadelphia, Pa.), HAT (Sigma Chemical Co.), RPMI-1640 medium, DMEM, and FBS (GIBCO, Grand Island, N.Y.) were used in the procedures described below.

C. parvum.—This is a Formalin-killed preparation; 7 mg *C. parvum*/ml was provided by the Burroughs Welcome Co., Research Triangle Park, N.C.

Antisera.—Mouse H-2 alloantisera were obtained from the Serum Bank, National Institute of Allergy and Infectious Disease, Bethesda, Md. The H-2 antigens of the RAG line (BALb/c) were demonstrated with an anti-D^d serum (catalog Y1-8-03-29-04) and the C3H BA antigens with an anti-K^k serum (catalog Y1-9-03-15-03).

C3H BA tumor cell suspensions.—For cell fusion, immunotherapy, or tumor challenge, we prepared cell suspensions from tumors transplanted as tissue fragments 14–17 days previously. After excision the tissue was minced by scalpel blades and enzymatically disaggregated in three separate incubations at 37°C while being shaken in a water bath. The tumor mince was incubated in 10 ml of Earle's balanced salt solution (pH 7.8) for 15 minutes. The supernatant was discarded, and 10 ml of M199 containing collagenase (250 μg/ml), hyaluronidase (0.12%), and salt-poor BSA (4% made from Sigma Chemical Co. fraction V BSA by dialysis with distilled water) was added and incubated for 45 minutes. The supernatant was again discarded and 10 ml of a 1% pronase solution (in M199) was added for 45 minutes. After this final incubation, 1 ml of 0.04% DNase was added, followed immediately by the addition of 30 ml of M199. The supernatant cells were retained, filtered through glass wool, and washed. Testing of this fraction by trypan blue exclusion has consistently shown a cell viability of 85% or greater.

Cell fusion.—To develop the HTC lines, we fused BA cells with RAG cells by using 35% PEG as the "fusogen." The BA cells were freshly dissociated and the RAG cells were harvested with 0.125% trypsin and 0.05% EDTA. Both cell types were washed in serum-free RPMI-1640 medium for removal of enzymes and serum. When 5×10^6 of each cell type was placed in round-bottom tubes, the cells were centrifuged at 250×*g* for 5 minutes at room temperature. The supernatants were removed, and the cells were gently resuspended in 0.5 ml of PEG for 8 minutes. Then 5 ml of serum-free RPMI-1640 medium was added, and the tubes were centrifuged at 250×*g* for 5 minutes. The supernatant was removed, and the cells were resuspended in RPMI-1640 medium containing FBS and were plated in small tissue culture flasks (25 cm^2) at a final concentration of 1×10^5 cells/flask. Control flasks of each parent cell were also plated. After 24 hours, the medium was replaced with HAT-RPMI-1640-selective medium (1×10^{-4} *M* hypoxanthine, 4×10^{-7} *M* aminopterin, and 1.6×10^{-5} *M* thymidine).

Flow cytometry of hybrid cells.—Flow cytometric analysis was done with a Coulter EPICS-V flow cytometer and sorter (Coulter Electronics Inc., Hialeah, Fla.). The excitation source was a 164-05 Spectra-Physics argon ion laser (Spectra-Physics Inc., Mountain View, Calif.) which was tuned to 488 nm with an output of 500 mW. Fluorescein—ethidium bromide fluorescence was collected through the following filters for two-color analysis: The barrier filter was a 510-nm interference filter, and the red fluorescence was separated from the green fluorencence with a 590-nm dichroic mirror. Glass LPF were placed in front of the red PMT (590 nm LPF) and the green PMT (515 nm LPF) to ensure that any scattered light escaping the interference filter through a manufacturing defect was not allowed to enter the PMT. We used the multiparameter data acquisition and display system of the EPICS-V to collect and display two-color fluorescence signals and light scatter signals. More detailed descriptions of the flow cytometric methodology are described elsewhere (*17*, *18*).

Flow cytometric analysis of H-2.—Cells to be used for immunofluorescence analysis were dispersed with trypsin and EDTA and, after dispersion was complete, were placed in PBS containing 0.1% sodium azide (PBS azide). Then, 2×10^6 cells of each type to be analyzed were incubated in the appropriate dilution of mouse anti-H-2 K^k or anti-H-2 D^d. At the end of this 4°C, 30-minute incubation, cells were diluted in PBS azide and washed twice in the cold. After being washed, the cells were placed in the appropriate dilution of a fluorescein-conjugated goat $F(ab')_2$ IgG anti-mouse IgG (Cappel Laboratories, Cochranville, Pa.). Cells were incubated in the conjugate for 30 minutes at 4°C. After this incubation, cells were washed twice in PBS azide while on ice and were then made ready for flow cytometric analysis.

Indirect immunofluorescence analysis on flow cytometers requires that dead cells be distinguished from live cells. Two drops from a Pasteur pipette of a solution of 20 μg ethidium bromide/ml of PBS azide were placed into each tube containing 2×10^6 fluorescein-stained cells in 1 ml of PBS azide. With this procedure nuclei of all dead cells stained with ethidium bromide, whereas live cells did not permit the penetration of ethidium bromide (*19*). Immunofluorescence profiles of each sample were obtained when identical high-voltage and gain settings were used. Gate windows were established such that green fluorescence signals were acquired for only those cells that did not fluoresce with ethidium bromide and had a light scatter intensity equal to that of cells and not of debris.

Immunotherapy.—Immunizations were given weekly. Those cell suspensions being irradiated were exposed to a cesium source and received 10,000 rad. When *C. parvum* was included in the immunizing preparations, it was added at 35 μg/10^7 tumor cells. The desired number of tumor cells was made up to 0.1 ml in M199 and was administered id to the abdominal area.

Tumor challenge.—C3H BA cell suspensions that had not been irradiated were injected id over the chest wall.

Statistics.—The effectiveness of each immunogen was evaluated by the determination of the survival times of mice that had received a tumor challenge after being immunized. The differences in immunogenicity were most apparent in the later stages of an experiment when fewer mice remained alive. Therefore, we used the generalized Savage (Mantel-Cox) method to compare the survival curves.

RESULTS

Hybrid Cell Characteristics

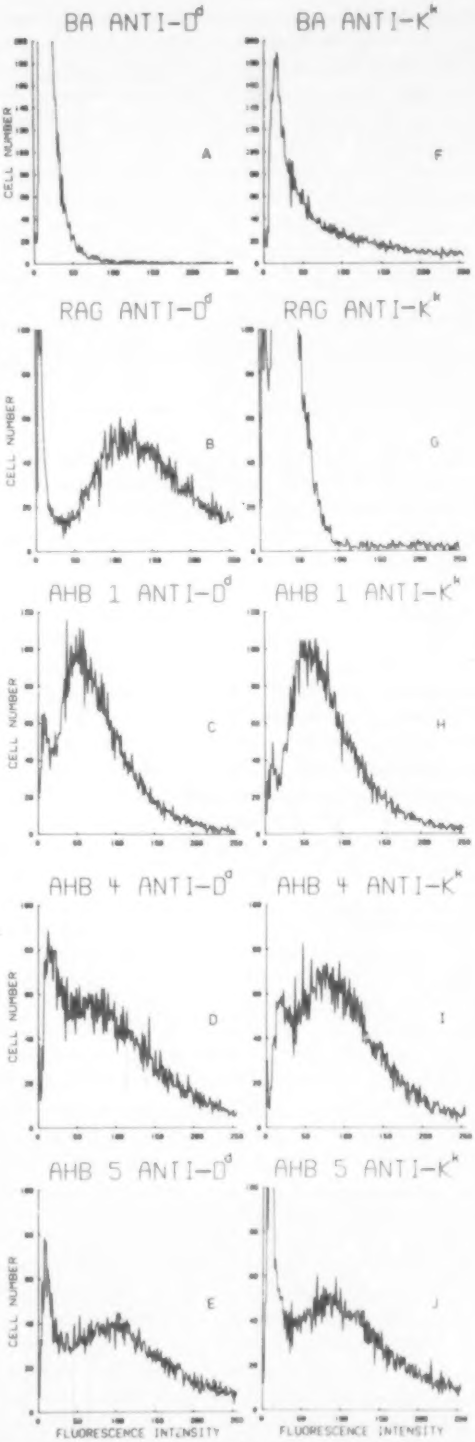
At 14 days after cell fusion, several colonies were observed in each HAT-containing flask. Because BA cells do not grow in culture and HPRT-deficient RAG cells died in control flasks grown in selective medium, these colonies were presumed to be hybrids. Each flask which attained confluence was designated as a noncloned AHB line (lines 1–7) and passaged. Three lines, AHB 1, 4, and 5, were selected for immunizing experiments on the basis of the practical consideration that they grew rapidly in culture. To confirm their hybrid origin, we analyzed AHB 1, 4, and 5 cells for expression of parental H-2 antigens by flow cytometry. Text-figure 1 illustrates that BA cells (derived from mice with the *H-2*^{K} haplotype) have an immunofluorescence profile positive for anti-K^k serum but not for anti-D^d serum and that RAG cells (derived from mice with the *H-2*^{D} haplotype) react positively with anti-D^d serum but not with anti-K^k serum. Each of the three hybrid cell lines analyzed showed immunofluorescence profiles positive for both anti-K^k and anti-D^d sera. Table 1 further demonstrates the hybrid origin of the cell lines by quantifying in each population the percentage of cells having a fluorescence intensity above an arbitrary level.

Syngeneic Tumor Cells as Immunogens

Syngeneic BA tumor cells and *C. parvum* were injected separately or together for 4 weeks (text-fig. 2). The survival time of those mice receiving *C. parvum* was on the average shorter than that of the untreated control group ($P<0.01$). Injections of BA tumor cells only, for 4 weeks, did not significantly affect the survival time when compared to that of the control group ($P>0.24$), although 2 of 15 mice remained tumor-free. When *C. parvum* was added to the BA cells, a single injection was ineffective, but four weekly injections resulted in prolonged survival ($P<0.001$) and 10 of 15 mice remained tumor-free.

HTC as Immunogens

AHB tumor lines 1, 4, and 5 were pooled and given as weekly injections. Each injection contained 3.3×10^6 viable cells of each hybrid (total, 9.9×10^6) and 35 µg *C. parvum*/10^7 tumor cells. All hybrid cells were preserved in liquid nitrogen until used and were given unirradiated unless otherwise indicated. Their viability after being frozen and thawed was consistently greater than 80%. The injected hybrid cells

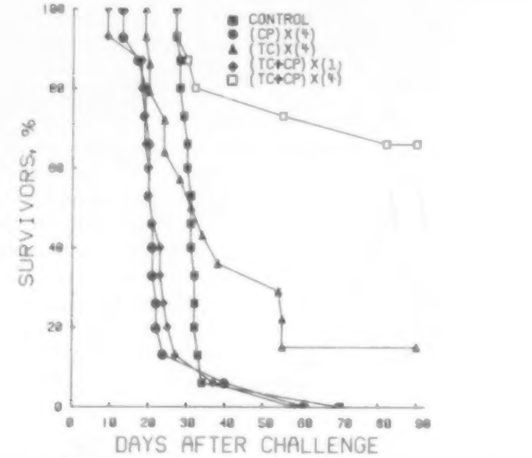


TEXT-FIGURE 1.—Fluorescence intensity of parent (BA, RAG) and hybrid (AHB 1, 4, and 5) cells as determined by flow cytometry. The anti-D^d antiserum identifies the H-2^d antigens of RAG cells. The anti-K^k antiserum identifies H-2^k antigens of BA cells. BA cells were freshly dissociated from tumor, whereas RAG and all hybrids were harvested from culture.

TABLE 1.—*H-2 antigens of parent and hybrid cells analyzed by fluorescent antibodies*

Cells	Percent of cells above channel 60[a]	
	Anti-D^d	Anti-K^k
Parental		
BA	4	47
RAG	82	15
Hybrids		
AHB 1	58	63
AHB 4	65	71
AHB 5	77	68

[a] Channel 60 is an arbitrary level of fluorescence intensity selected so that those cells with only background fluorescence could be distinguished from those that have absorbed anti-H-2 fluorescent antibodies.



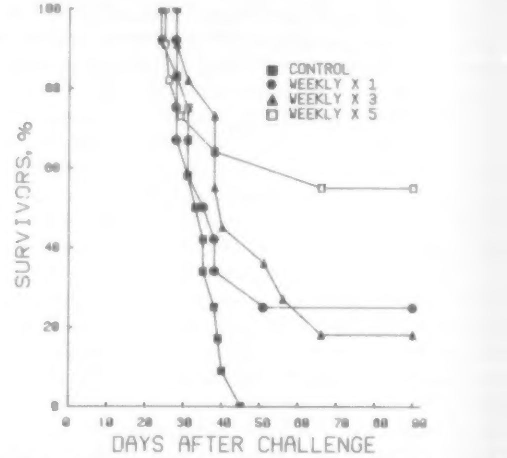
TEXT-FIGURE 2.—Comparison of survival of groups of mice receiving no treatment (CONTROL), 35 μg *C. parvum* id weekly for 4 wk [(CP)×(4)], 10^7 irradiated tumor cells id weekly for 4 wk [(TC)×(4)], and 10^7 irradiated tumor cells mixed with 35 μg *C. parvum* id weekly for 1 wk [(TC+CP)×(1)] and for 4 wk [(TC+CP)×(4)]. The weekly injections ended 7 days before the challenge with 2×10^6 live BA cells. Groups contained 14–15 mice.

formed small nodules which disappeared by 7 days. A challenge of 1.2×10^6 viable BA cells obtained from freshly dissociated tumor was given id over the chest wall 7 days after the last immunizing injection. All mice were challenged on the same day in a particular experiment.

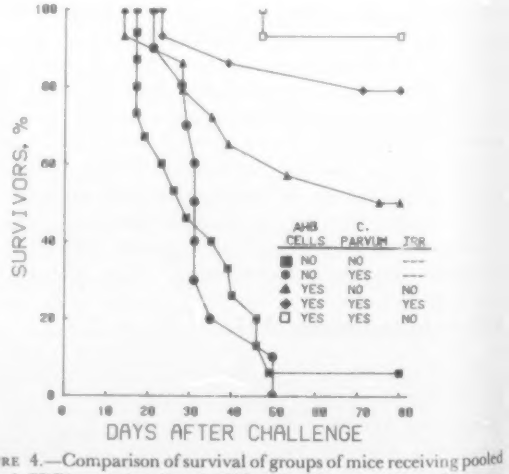
An experiment in which the hybrid cells were given weekly for 1, 3, and 5 weeks is shown in text-figure 3. All control-group unimmunized animals died by day 45. A single injection of pooled hybrid cells resulted in 3 of 12 animals remaining tumor-free, but the difference in the survival time was not significant($P>0.16$). Three weekly injections prolonged the survival time ($P<0.009$), but only 2 of 11 remained tumor-free. Five weekly injections improved overall survival time ($P<0.007$), and 6 of 11 mice were tumor-free (all of these three comparisons were against the survival time in the control group). The difference between one and five injections did not attain significance at the 0.05 level.

Adjuvant and Radiation Effects

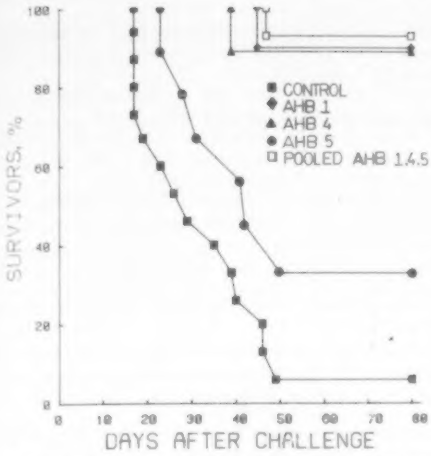
The role of *C. parvum* and a comparison of viable versus irradiated hybrids were evaluated in the experiment shown in text-figure 4. All test groups of mice received weekly injections for 5 weeks. When 35 μg of *C. parvum* was given alone, no significant change in the survival time from that of the control group was observed. Pooled hybrid cells in the absence of *C. parvum* were immunogenic compared with the control group ($P<0.005$), and 7 of 14 animals remained tumor-free; however, when *C. parvum* was added to the hybrid cells, the improvement in the survival time was even greater ($P<0.02$ compared to the survival obtained when *C. parvum* was not added to the hybrids) and 14 of 15 mice remained tumor-free. When the hybrid cells were irradiated and given with *C. parvum*, the decrease in the survival time



TEXT-FIGURE 3.—Comparison of survival of groups of mice receiving pooled unirradiated hybrids with 35 μg *C. parvum*/10^7 tumor cells. Groups were immunized for 1, 3, or 5 wk (WEEKLY×1, 3, and 5); challenge was with 1.2×10^6 live BA cells 7 days after the last immunization. Groups contained 11–12 mice.



TEXT-FIGURE 4.—Comparison of survival of groups of mice receiving pooled irradiated (IRR) or unirradiated AHB cells with or without *C. parvum*. Immunizations were given for 5 wk; challenge was with 1.2×10^6 live BA cells. Groups contained 10–15 mice.



TEXT-FIGURE 5.—Comparison of survival of groups of mice receiving five weekly immunizations with single or pooled unirradiated hybrids (AHB 1, 4, and 5) with *C. parvum*. Challenge was with 1.2×10^6 live BA cells. Groups contained 10–15 mice.

was not significant when compared to that when unirradiated hybrids were given with *C. parvum* ($P>0.28$).

Single Hybrid Lines Versus Pooled Hybrid Lines

The immunogenicity of individual hybrid lines was compared with the pool of three hybrids in the experiment shown in text-figure 5. This experiment was performed concurrently with the experiment presented in text-figure 3, and the control and pooled groups were common to both experiments. The immunizing cells for all groups were unirradiated, had *C. parvum* added, and were given as five weekly injections before the challenge. AHB lines 1 and 4 both produced an improvement in the survival time ($P<0.0001$), which is similar to that of the pool of three hybrids. In contrast AHB line 5 was weakly immunogenic, and the survival curve for this group did not differ significantly from that of the control group ($P>0.06$).

Multiple comparisons have been made with the data of each experiment. They might inflate the type I error in testing the equality of the survival curves beyond the 0.05 level. However, most of the *P*-values that we cited to establish differences are fairly low, which tends to justify our claims.

DISCUSSION

We have demonstrated in this study that the BA tumor cell line which will not grow in culture can be fused readily with the RAG cell line which does grow in culture to produce hybrid cell lines that can grow apparently indefinitely in culture and will produce large numbers of cells for immunization. The results also show that some cell lines so generated can serve very effectively as immunogens in protecting against the targeted parent tumor (BA). Thus in the animal model we can reach several of the goals that we hope to attain in human patients. In additon, we have examined several methodologic questions relevant to optimal immunization.

In the experiment shown in text-figure 2, we determined some of the background parameters relevant to antitumor immunity in this model. Four weekly injections of irradiated tumor cells did not protect the mice, which indicates that this tumor is poorly immunogenic. The adjuvant *C. parvum* which we used in these studies did not produce a survival advantage when given independently in the small doses desirable for an adjuvant role (*1, 4, 20*). However, adjuvant-facilitated tumor cell recognition does occur in this model when BA cells plus *C. parvum* are given for four weekly injections (text-fig. 2). This tumor was found to require several weekly immunizations, although a single injection has been adequate in other models (*4, 20*). When the question of single versus serial injections was looked at with hybrids as immunogens (text-fig. 3), significant survival effects were again seen only with three and five weekly injections.

The beneficial effect of an adjuvant when added to syngeneic tumors cells has been demonstrated in animal models of active specific immunotherapy (*1–4*). We wished to know if an adjuvant would also assist hybrids as immunogens. The hybrid cells in these experiments express histocompatibility antigens ($H\text{-}2^d$) foreign to the mouse strain (C3H/He) of origin of the BA tumor. The presumed TAA of the BA tumor would be expressed in association with the foreign $H\text{-}2^d$ antigens on the surface membrane of these hybrids. We surmised that the foreign $H\text{-}2^d$ might fulfill an adjuvant role and the addition of *C. parvum* to hybrids might be noncontributory. Indeed, we did find that HTC without adjuvant were effective immunogens; however, the addition of *C. parvum* improved survival significantly beyond that attained with hybrids alone (text-fig. 4).

Hybrid cells can be injected for immunizing purposes when fully viable as contrasted with killed or irradiated cells, which is the requirement for syngeneic cells. Parkman (*9*) and Kim et al. (*12*) found that injected viable hybrids never grow lethally in the syngeneic hosts of the target tumor but may be observed to grow briefly before an immune response develops. Our hypothesis was that immunization with viable hybrid cells might be superior to immunization with irradiated hybrids because the viable hybrid cells remain alive and proliferate in the host until their immunologic rejection. However, as seen in text-figure 4, irradiation did not significantly alter the immunogenic function of these hybrids. This retention of immunogenic function is supported in part by the observation that irradiated tumor cells do persist for several days at the injection site (*21*) and that they may function as immunogens for a time similar to the interval noted for unirradiated hybrids.

Therapeutic effectiveness has been noted to vary among hybrid lines derived from the same parent cells (*9, 12*). The hybrid lines AHB 1 and 4 were individually immunogenic at a level equal to that of a pool of all three lines, whereas AHB 5 was strikingly ineffective (text-fig. 5). A troublesome problem is that hybrid cells may lose critical surface antigens required for antitumor immunization. This may occur through elimination of chromosomes or through extinction of the expression of chromosomes although the chromosomes themselves are retained. Hybrid lines AHB 1 and 4 have been maintained in culture for more than 1 year and still retain the relevant tumor antigens. Whether AHB 5 lost immunogenicity with time or was never very protective cannot be determined from our experiments, inasmuch as AHB 5 was not used separately until after many passages in culture. However, these results demonstrate the retention of relevant antigens in two of three lines.

Hybrids may also be expected to vary in immunogenicity as a consequence of the postulated antigenic heterogeneity within the tumor parent (*22-24*). A hybrid line might antigenically represent a very uncommon subpopulation and be totally ineffective when used as a single immunogen, but hybrid lines might also be the means for totally representing an entire tumor if several hybrid lines are pooled. Hence pooled HTC provide a means of representing all populations within a tumor in adequate antigenic doses for the initiation of multideterminant antitumor immunity.

We have not directly compared the immunogenicity of individual hybrid lines versus parental BA cells in these experiments. Such comparisons are under way with a larger series of hybrid lines in experiments in which our particular interest is the evaluation of those parameters which may be predictive of greater immunogenicity.

Inhibitory Effect of Interferon on the Growth of Spontaneous Mammary Tumors in Mice[1,2,3,4]

Erik De Clercq,[5] **Zhen-Xi Zhang,**[5,6] **Kris Huygen,**[7] *and* **Roger Leyten**[8,9]

ABSTRACT—Partially purified mouse interferon type I (Mu IFN-β), crude mouse interferon type II (Mu IFN-γ) serum, and the interferon inducer polyinosinic acid-polycytidylic acid (poly I:C) were evaluated for their effects on the growth of spontaneously occurring mammary carcinomas in BALB/c mice. As soon as their tumors had reached a palpable size (diameter: 3–5 mm), the mice received three ip injections of Mu IFN-β, Mu IFN-γ, or poly I:C per week for 6 weeks. A significant (fourfold to fivefold) reduction in tumor size was achieved with Mu IFN-β (at 10^6 U/mouse), Mu IFN-γ (at 10^3 U/mouse), and poly I:C (at 1 mg/mouse). A similar reduction in tumor size was noted when the mice were treated with cyclophosphamide (2.5 mg/mouse, three ip injections per wk for 6 wk). Treatment with Mu IFN-β combined with Mu IFN-γ resulted in a greater tumor growth-inhibitory effect than treatment with either Mu IFN-β or Mu IFN-γ alone. In addition to inhibiting the growth of primary tumors, interferon also reduced the incidence of lung metastases. However, complete tumor regression was not observed in any mouse while under interferon therapy.—JNCI 1982; 69:653–657.

IFN therapy has been attempted in a number of patients with osteosarcoma, myeloma, lymphoma, melanoma, breast cancer, lung cancer, or other neoplasms (*1*). Partial or complete remissions have been observed in only a small percentage of the patients, ranging from 0% of the patients with lung cancer or diffuse histiocytic lymphoma to approximately 30% of the patients with myeloma or breast cancer. Of a series of 17 patients with advanced breast cancer who were treated with human IFN-α, 6 patients achieved a partial remission, 1 patient showed a less than partial remission, and 10 patients did not respond; none of the patients acquired a complete remission (*2*).

Although IFN has been administered to a relatively large number of patients with breast cancer, there is little, if any, evidence that IFN may cause regression of spontaneous or carcinogen-induced mammary tumors in animal models. The only study pertaining to the effect of IFN treatment on mammary tumors in animals (mice) is that of Came and Moore (*3, 4*). These authors found that IFN treatment initiated early in life (at the age of 6 wk) could retard the appearance of spontaneous mammary carcinomas in RIII mice. However, they noted no such delay in tumor appearance if IFN treatment was started at 22 weeks of age, and they did not attempt to assess the potential antitumor effects of IFN in mice that had already developed mammary tumors.

We have now evaluated the effects of IFN and the IFN inducer poly I:C in mice that had developed a palpable mammary tumor at the time treatment was started. In addition to our evaluation of the effects of Mu IFN-β, we have determined the effects of Mu IFN-γ, since IFN-γ has, per unit of antivirus activity, a significantly greater anticellular activity than IFN-β or IFN-α (*5, 6*). Furthermore, Mu IFN-γ preparations have been shown to inhibit the growth of transplanted osteogenic sarcomas in mice at a dose a hundredfold less than that required for Mu IFN-β (*7*). In view of the apparent synergism in the antivirus activities of Mu IFN-β and Mu IFN-γ (*8*), which was recently extended to the antitumor effects of Mu IFN-β and Mu IFN-γ (*9*), we have also investigated the combined effects of Mu IFN-β and Mu IFN-γ on the growth of mammary tumors. This investigation was further prompted by our recent observations (*10*) that treatment with Mu IFN-β combined with Mu IFN-γ significantly increased the survival of mice inoculated with murine leukemia L1210 cells.

MATERIALS AND METHODS

Animals.—Female BALB/c mice were used throughout. Approximately 20% of these mice developed mammary carcinomas. The mice were bred in the Laboratory Animal Center (Proefdierencentrum) of the University of Leuven and were followed regularly for the development of mammary tumors. Treatment was started as soon as the tumor was palpable (at a diameter of 3–5 mm), which occurred in the mice at an average age of 189 days (range: 110–318 days).

Compounds.—Poly I:C was constituted from the individual homopolymers polyinosinic acid and polycytidylic acid, both purchased from P-L Biochemicals, Inc., Milwaukee, Wis. The sedimentation coefficients corrected to water at 20°C of polyinosinic acid and polycytidylic acid were 9.4 *s* and 10.0 *s*, respectively. Poly I:C was prepared at 1 mg/ml in Dulbecco's phosphate-buffered saline. Mu IFN-β was induced with Newcastle disease virus in mouse L-929 fibro-

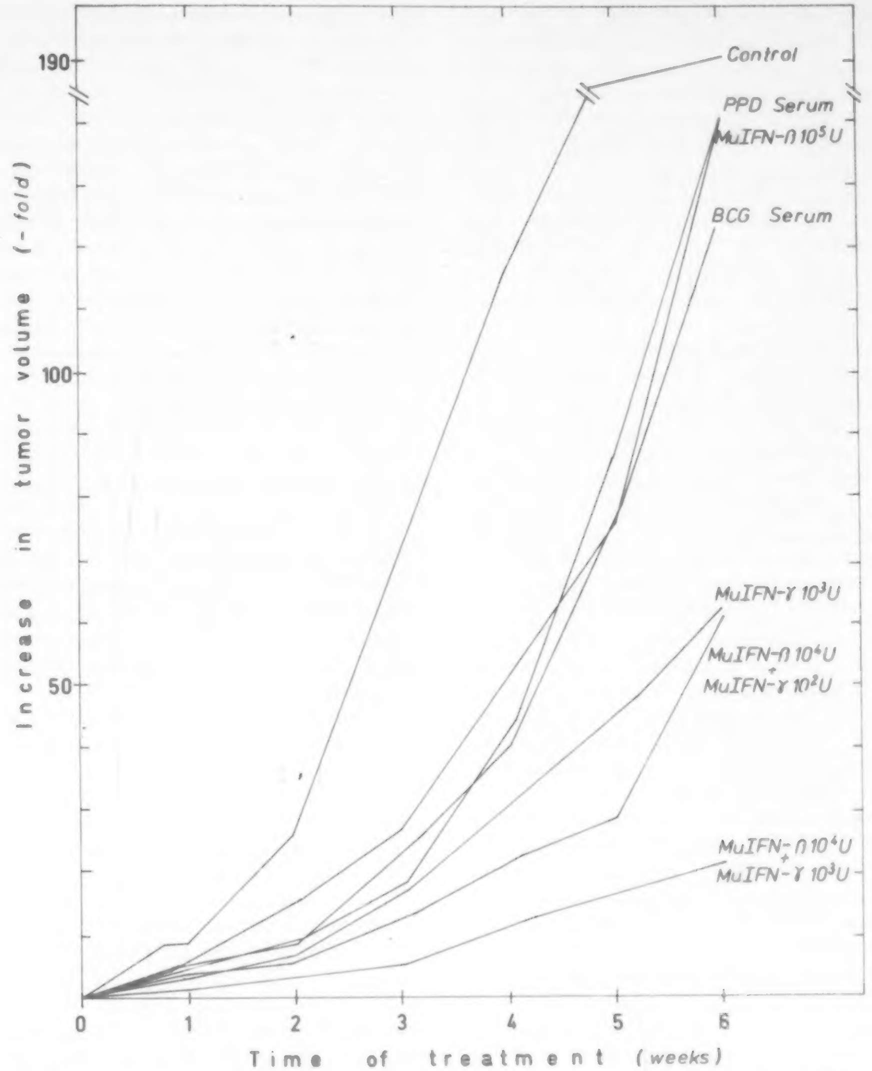
TEXT-FIGURE 1.—Inhibitory effects of poly I:C [(I)n·(C)n], Mu IFN-β, Mu IFN-γ, and cyclophosphamide (CP) on the growth of mammary tumors in BALB/c mice. Number of mice per group: 53 in the control (untreated) group, 21 in the group treated with 0.2 mg poly I:C/mouse, 21 in the group treated with 10^6 U Mu IFN-β, 22 in the group treated with 2.5 mg cyclophosphamide/mouse, 20 in the group treated with 1 mg poly I:C/mouse, and 32 in the group treated with $10^{3.3}$ U Mu IFN-γ/mouse.

blasts, as described previously (*11*). It was purified by $(NH_4)_2SO_4$ precipitation to a specific activity of 10^6 U protein/mg. Mu IFN-γ was obtained from the sera of Swiss mice that had been sensitized with BCG (immuno-BCG GL2, grown as a surface pellicle) (1 mg/mouse, iv), boosted 2 weeks later with PPD (1 mg/mouse, iv), and bled 5 hours after the PPD injection. The specific activity of the Mu IFN-γ preparation was 60 U/mg protein. BCG serum was derived from mice that had been given iv injections of BCG 2 weeks before they were bled and their sera sampled (IFN titer: <10 U/ml). PPD serum was derived from mice that had received iv injections of PPD 5 hours before they were bled and their sera sampled (IFN titer: <10 U/ml). Cyclophosphamide (Endoxan) was purchased from Cilag-Chemie, Herentals, Belgium.

Treatment.—Mice bearing palpable mammary tumors were allocated at random to the different treatment groups. Treatment consisted of three ip injections per week for 6 weeks. Poly I:C was administered at either 0.2 mg/mouse (8 mg/kg) or 1 mg/mouse (40 mg/kg). Mu IFN-β was given at 10^4, 10^5, or 10^6 U/mouse, Mu IFN-γ at 10^2, 10^3, or $10^{3.3}$ U/mouse, and cyclophosphamide at 2.5 mg/mouse (100 mg/kg). BCG serum and PPD serum were administered at 0.2 ml/mouse. The number of mice per group is indicated in the legends to the text-figures.

Tumor volume measurements.—The length and width of the mammary tumors were determined weekly with calipers, and tumor volume was calculated according to the formula



TEXT-FIGURE 2.—Inhibitory effects of BCG serum, PPD serum, Mu IFN-β, Mu IFN-γ, and combinations of Mu IFN-β and Mu IFN-γ on the growth of mammary tumors in BALB/c mice. Number of mice per group: 53 in the control (untreated) group, 20 in the group treated with PPD serum, 18 in the group treated with 10^5 U Mu IFN-β/mouse, 22 in the group treated with BCG serum, 16 in the group treated with 10^3 U Mu IFN-γ/mouse, 20 in the group treated with the combination of Mu IFN-β (10^4 U/mouse) and Mu IFN-γ (10^2 U/mouse), and 20 in the group treated with the combination of Mu IFN-β (10^4 U/mouse) and Mu IFN-γ (10^3 U/mouse).

$V = 4/3\ \pi L/2(W/2)^2$. The number of tumors arising in individual mice varied from 1 to 7; the frequency of mice developing 1, 2, 3, 4, 5, 6, or 7 tumors was 30, 25.5, 24.5, 9, 6.5, 3.5, and 1%, respectively. For those mice that developed more than 1 tumor, tumor volumes were measured separately. These tumor volumes were combined in the calculation of the total tumor volume per mouse, and the tumor volumes indicated in text-figures 1 and 2 refer to the average tumor volumes per mouse.

Statistical analysis.—Differences in tumor volume per mouse between the control (untreated) and treated groups at the end of the 6-week treatment period were assessed for statistical significance by Student's *t*-test.

Histologic examination.—Tumor specimens removed from control mice were identified as mammary carcinoma upon microscopic examination (courtesy of Dr. H. Sobis, Rega Institute for Medical Research). For those mice that were killed at the end of the 6-week treatment period, the lungs were examined macroscopically and microscopically for metastases.

RESULTS

In the first experiment we evaluated the tumor-inhibiting properties of the following treatment regimens: poly I:C at 0.2 and 1 mg/mouse, Mu IFN-β at 10^6 U/mouse, Mu IFN-

pages tightly bound
best copy available

γ at $10^{3.3}$ U/mouse, and cyclophosphamide at 2.5 mg/mouse. All treatment regimens effected a significant reduction in tumor growth as compared to the tumor growth seen in control (untreated) mice (text-fig. 1). At 0.2 mg/mouse, poly I:C reduced the increase in tumor volume from 190-fold to a hundredfold after 6 weeks of treatment ($P<0.05$). When the poly I:C dose was raised to 1 mg/mouse, the increase in tumor volume was reduced to 35-fold ($P<0.001$). A similar reduction in tumor growth ($P<0.001$) was achieved with Mu IFN-γ at $10^{3.3}$ U/mouse. Mu IFN-*β* at 10^6 U/mouse and cyclophosphamide at 2.5 mg/mouse reduced the increase in tumor volume to about 47-fold ($P<0.005$) (text-fig. 1).

In the second experiment various additional treatment regimens were compared for their antitumor potentials, viz., BCG serum, PPD serum, Mu IFN-*β* at 10^4 and 10^5 U/mouse, Mu IFN-γ at 10^2 and 10^3 U/mouse, and combinations of Mu IFN-*β* (10^4 U/mouse) and Mu IFN-γ (10^2 U/mouse) and Mu IFN-*β* (10^4 U/mouse) and Mu IFN-γ (10^3 U/mouse) (text-fig. 2). While BCG serum, PPD serum, Mu IFN-γ at 10^2 U/mouse, and Mu IFN-*β* at 10^4 or 10^5 U/mouse did not significantly inhibit tumor growth, Mu IFN-γ at 10^3 U/mouse reduced the increase in tumor volume from 190- to 63-fold ($P<0.05$). This increase in tumor volume was further decreased to only 22-fold if Mu IFN-γ (10^3 U/mouse) was combined with Mu IFN-*β* (10^4 U/mouse) ($P<0.005$). Similarly, Mu IFN-*β* at 10^4 U/mouse combined with Mu IFN-γ at 10^2 U/mouse significantly reduced tumor growth ($P<0.05$) (text-fig. 2), although either IFN dose regimen used separately did not confer an appreciable diminution of tumor size (data not shown).

At the end of the 6-week observation period, the mice were killed and their lungs examined macroscopically and microscopically for metastases. The following treatment groups were examined: mice treated with BCG serum, PPD serum, cyclophosphamide (2.5 mg/mouse), Mu IFN-γ ($10^{3.3}$ U/mouse), and Mu IFN-*β* (10^4 U/mouse) combined with Mu IFN-γ (10^2 U/mouse). Lung metastases were detected in 84% of the control (untreated) mice. Of the mice treated with BCG serum and PPD serum, the frequency showing lung metastases amounted to 77 and 75%, respectively; this is not significantly different from the frequency of mice showing lung metastases in the control group. However, the other treatment regimens brought about a significant reduction in the percentage of mice developing lung metastases; i.e., cyclophosphamide (2.5 mg/mouse) resulted in a 52% reduction ($P<0.05$), Mu IFN-γ ($10^{3.3}$ U/mouse) resulted in an 18% reduction ($P<0.001$), and Mu IFN-*β* (10^4 U/mouse) plus Mu IFN-γ (10^2 U/mouse) resulted in a 60% reduction ($P=0.05$).

DISCUSSION

The results of our study demonstrate that both IFN and poly I:C reduced, but did not completely suppress, the growth rate of mammary carcinomas in BALB/c mice; that the tumor-inhibiting effects of IFN and poly I:C were dose-dependent; that Mu IFN-γ, per antiviral unit, exerted a significantly greater antitumor effect that did Mu IFN-*β*; that the antitumor activity of low doses of Mu IFN-γ (10^3 U/mouse) and high doses of Mu IFN-*β* (10^6 U/mouse) was comparable to that of the standard anticancer drug cyclophosphamide; that IFN reduced not only the growth of primary mammary tumors but also the formation of metastases in the lungs; and that Mu IFN-γ combined with Mu IFN-*β* led to a markedly greater antitumor activity than either IFN alone. However, tumors did not regress completely in any mouse treated with IFN.

The antitumor effects described here for IFN and poly I:C extend previous investigations on the antitumor activity of IFN and poly I:C in a number of experimental murine models, including virus-induced tumors, chemically induced tumors, transplantable tumors, and spontaneous tumors [for a review, *see* (*12*)]. Of direct relevance to the present study are the results obtained with IFN in the prophylaxis and therapy of spontaneous tumors. If given prophylactically, i.e., from the day of birth, IFN delayed the appearance of lymphoid leukemia in AKR mice (*13*), but even if treatment was started after clinical diagnosis of lymphoma, IFN substantially increased the mean survival time (*14*). Yet tumor regression did not occur in any of the leukemic AKR mice treated with IFN, and all mice eventually died from the disease. Hence the results obtained with IFN in the treatment of spontaneous murine leukemia are quite comparable to those obtained in the present study, in that IFN only partially suppressed tumor growth and did not cure the host of its neoplasia.

At a dose of 10^3–$10^{3.3}$ U/mouse (text-figs. 1, 2), Mu IFN-γ brought about the same reduction in growth of mammary tumors as did Mu IFN-*β* at a dose of 10^6 U/mouse (text-fig. 1). In C57BL/6 mice inoculated with osteogenic sarcoma cells, a 7-day course of Mu IFN-γ at 600 U/mouse/day was as effective in inhibiting tumor development as was a 7-day course of Mu IFN-*β* at 60,000 U/mouse/day (*7*); in C3HeB/FeJ mice bearing transplantable MC-36 sarcomas, direct intratumoral injection of Mu IFN-γ at 300 U/mouse/day for 3–4 weeks reduced the tumor mass by 98%, whereas a similar treatment regimen for Mu IFN-*β* did not show any protective activity (*15*). The Mu IFN-γ preparations that were used in these previous studies (*7, 15*) as well as in ours were from sera of mice that had been sensitized with BCG, challenged 2–3 weeks later with PPD, and exsanguinated 3–5 hours after PPD injection. These sera contained not only IFN but also other lymphokines (e.g., migration inhibitory factor and interleukin 1), released concomitantly with IFN. These lymphokines may have contributed to the antitumor effects of the Mu IFN-γ preparations. Some lymphokines might themselves inhibit tumor growth, whereas others might modulate (either diminish or potentiate) the antitumor activity of Mu IFN-γ.

Several mechanisms could be envisaged to account for the inhibitory effects of Mu IFN-*β* and Mu IFN-γ on mammary tumor growth (*16*), i.e., *a*) inhibition of mammary tumor virus multiplication [which would be unlikely, according to the findings of Came and Moore (*3*)], *b*) direct antimitotic action on the tumor cells, *c*) increased expression of cell surface antigens, *d*) activation of the cytotoxicity of macrophages for tumor cells, and *e*) stimulation of the NK activity and ADCC of lymphocytes for tumor cells. The antitumor activity of IFN may be achieved by a cooperation of some of these effector mechanisms, i.e., *c* and *e*. As suggested by Yagi and Bekesi (*17*), exposure of the mammary tumor cells to IFN may induce alteration in the antigenic composition of the cells (*c*). This increased antigenicity may lead to a heightened host recognition and immune response against the growing tumor, which could, in turn, be further enhanced by contact of the host cells with IFN (*e*).

If one assumes that the antitumor activity of the Mu IFN-γ preparations reside in Mu IFN-γ per se, which remains to be proved, one could readily explain why the inhibitory effects of Mu IFN-γ on mammary tumor growth should exceed those of Mu IFN-β. Indeed, IFN-γ is a far more potent anticellular agent than IFN-β or IFN-α (*5, 6*) and is also far more active as an immunoregulatory agent than IFN-β or IFN-α (*18, 19*). This superiority may extend to various other properties of IFN, e.g., its enhancing effects on macrophage activity, cell surface antigen expression, NK activity, and ADCC. As has been demonstrated recently by Catalona et al. (*20*), IFN-γ is a potent stimulator of both NK activity and ADCC.

In keeping with the observations of Fleischmann et al. (*9*) and our own observations (*10*) in mice inoculated with P388 or L1210 cells, combined administration of Mu IFN-β and Mu IFN-γ effected a much greater inhibition of mammary tumor growth than did either IFN given alone (text-fig. 2). The reason(s) for this synergism remain unclear but may be related to differences in the mode of action of Mu IFN-β and Mu IFN-γ.

Influence of Cause-of-Death Assignment on Time-to-Tumor Analyses in Animal Carcinogenesis Studies[1,2]

Ralph L. Kodell,[3] John H. Farmer,[3,4] David W. Gaylor,[3] *and* Alexander M. Cameron[3,5]

ABSTRACT—The importance of cause-of-death determination in an animal carcinogenesis study with respect to estimation of time-to-tumor distributions of internally occurring (occult) tumors is discussed. A nontechnical description of time-to-tumor estimation is presented. The information obtained from time-to-tumor estimation when cause-of-death designation was used is illustrated for liver tumors in female mice of the inbred strain BALB/cStCrlfC3Hf/Nctr from the ED_{01} study with *N*-2-fluorenylacetamide done at the National Center for Toxicological Research. A time-to-tumor analysis of reticulum cell sarcoma data from the same study has provided insight into some difficulties involved in routine case-by-case determination of cause of death. A more flexible system for assigning of cause of death to dead animals and cause of morbidity to moribund animals is described as a way to improve cause-of-death assignment.—JNCI 1982; 69:659–664.

Variation in reported latent periods among various neoplasms has been observed for both humans and experimental animals. This variation has led investigators of potential chemical carcinogens to recognize the importance of time to occurrence of spontaneous and induced tumors in animal bioassay studies in addition to the importance of simply the frequency of tumor occurrence. There has been no clear consensus due to several problems in the colleotion of data as to what constitutes a proper time-to-tumor analysis. The purpose of this paper is threefold: 1) to demonstrate that assignment of cause of death of each animal enhances most statistical analyses of time to tumor, 2) to show by example the extent to which the analysis is sensitive to the correct assignment and use of cause of death, and 3) to suggest a more flexible method of assigning cause of death which does not place unrealistic constraints on the examining pathologist.

In the context of this paper, the term *time to tumor* will mean the time from the beginning of an experiment until the time when a tumor is *first detectable* by the most appropriate observation method. For externally observable tumors, accurate measurement of time to grossly visible tumor is possible because constant surveillance can be maintained. For internally occurring (occult) tumors, because time to tumor as defined above means the time when a tumor is just large enough to be observed histologically, exact time to tumor cannot be measured inasmuch as histologic examination will not likely be conducted at the instant of first histologic detectability.

The three basic problems that have hampered statistical analyses of time-to-tumor data are inherent in the manner in which animal bioassay data are gathered. Animals that die (or are otherwise removed) without a particular tumor of interest during the course of an experiment constitute right-censored observations with respect to the time-to-tumor probability distribution, because it is only known that the animals might have developed a tumor sometime in the future. Animals that die (or are removed) for reasons other than an occult tumor of interest but that have already developed such a tumor (i.e., incidental tumor) constitute left-censored observations with respect to the time-to-tumor distribution, because it is only known that they developed a tumor sometime in the past. Finally, animals that die as a result of an occult tumor of interest (i.e., fatal tumor) constitute not only left-censored observations with respect to time to tumor but also the observed tumors arise from a biased sampling mechanism, namely, death from the tumor of interest.

Various parametric models for the analysis of time-to-tumor data have been proposed in the literature. For example, Albert and Altshuler (*1*) proposed a version of the lognormal probability distribution for time to tumor, as an extension of the work of Druckrey (*2*). Peto and Lee (*3*) discussed analyzing time-to-tumor data with the Weibull distribution, as earlier proposed by Pike (*4*). Hartley and Sielken (*5*) developed the general product model (which includes dose of carcinogen in addition to time to tumor) as an extension of earlier work by Armitage and Doll (*6*). Kodell and Nelson (*7*) proposed fitting independent Weibull distributions of time to onset of tumor and time to death after onset, with the assumption that the difference between fatal and incidental occurrence of tumors could be distinguished.

An early nonparametric approach was proposed by Hoel and Walburg (*8*) who first recognized that different animals provide different kinds of time-to-tumor information, dependent on the censoring involved. For externally observed or rapidly lethal tumors, they proposed estimation of the time-to-tumor distribution by the nonparametric survival estimator of Kaplan and Meier (*9*), because only right censoring is involved in those cases. For strictly nonlethal occult tumors, Hoel and Walburg (*8*) suggested nonparametric time-to-tumor estimation that uses the available time-to-tumor information in each of the right-censored and left-censored (but unbiased) observations. Peto (*10*) suggested testing methods for time-adjusted comparisons of tumor rates, which take into account the censoring-deter-

mined time-to-tumor information provided by each animal. An enlargement of Peto's work has resulted in a comprehensive testing methodology for animal carcinogenesis bioassays proposed by the International Agency for Research on Cancer (*11*).

The nonparametric time-to-tumor estimation procedure illustrated in the present paper was developed by Kodell et al. (*12*) as an extension of the estimation procedures of Kaplan and Meier (*9*), Hoel and Walburg (*8*), and Kodell and Nelson (*7*), whereas many of the underlying concepts overlap those of the testing procedure of Peto (*10*) and Peto et al. (*11*). The estimation procedure is based on the assumptions that each animal in a carcinogenesis bioassay can be assigned an appropriate cause of death upon necropsy or subsequent histopathologic examination and that causes of death (or removal) other than the tumor of interest censor the time to onset of tumor or time to death after onset in a noninformative manner.

Let $S(t)$ represent the net probability of not developing the tumor of interest by time t, and let $P(t)$ represent the net probability of not dying from the tumor of interest by time t, both conditional on survival with respect to all other causes of death up to time t. The respective estimators $\hat{P}(t)$ and $\hat{S}(t)$ of $P(t)$ and $S(t)$ proposed by Kodell et al. (*12*) are the Kaplan-Meier survival estimator (*9*) and the product of the Kaplan-Meier survival estimator and "one minus" the Hoel-Walburg estimator of prevalence of a nonlethal disease (*8*). Under the condition that the prevalence $1-S(t)/P(t)$ of the tumor of interest is a monotone nondecreasing function of t, the estimator $\hat{P}(t)$ is a generalized maximum likelihood estimator of $P(t)$ and $\hat{S}(t)$ coincides with the generalized maximum likelihood estimator of $S(t)$ over certain time intervals. The related estimators of Dinse and Lagakos (*13*) and B. W. Turnbull and T. J. Mitchell [Nonparametric estimation of the distributions of time to onset and time to death for specific diseases in survival-sacrifice experiments. Presentation at the meeting of the Biometric Society (ENAR), March 16–18, 1981, in Richmond, Va.], which do not restrict the prevalence to be monotone, may also be used to estimate the distributions of time to tumor and time to death. These estimators also depend on the important condition that fatal and incidental observations of the tumor of interest can be distinguished through the assignment of a cause of death for each animal. It is this condition that makes the functions $S(t)$ and $P(t)$ identifiable (*see 14*), thus permitting estimation of the time-to-tumor distribution function $1-S(t)$.

When an analysis is restricted to a particular type of tumor, it is only necessary to determine whether the particular tumor type under consideration caused the death of an animal. If not, then the exact cause of death is not required. Admittedly, cause-of-death determination requires a subjective judgment on the part of pathologists, and such a requirement sometimes places unfair constraints on them. The intent of this paper is to demonstrate the desirability of assigning cause of death (mortality) or illness (morbidity) whenever possible, to present a real-data example of the effect of misclassification of cause of death, and to suggest a more flexible way of assigning cause of death that will be acceptable to pathologists and statisticians alike. A theoretical investigation of the effects of misclassification of cause of death has been presented by Lagakos (*14*) in a testing context.

DATA-BASED PERFORMANCE ASSESSMENT

Application of the time-to-tumor estimation procedure of Kodell et al. (*12*) to data obtained from a large-scale carcinogenesis bioassay (the so-called "ED$_{01}$ Study") conducted at the National Center for Toxicological Research illustrates the importance of cause-of-death determination. The procedure is first applied to liver tumor data (hepatocellular adenomas and carcinomas) and is then applied to reticulum cell sarcoma data (including all types and organs).

Complete details of the design and execution of the ED$_{01}$ study, as well as of several selected analyses, are provided in the proceedings of the symposium Innovations in Cancer Risk Assessment (ED$_{01}$ Study) presented by the ED$_{01}$ Working Group (*15*). The study involved continuously feeding 2-FAA, a known bladder and liver carcinogen in mice, to inbred female BALB/cStCrlfC3Hf/Nctr mice until their death or their removal when moribund or until their scheduled killing at times ranging from 9 months (273 days) to 33 months (1,001 days). Concentrations of 2-FAA in the feed were 0, 30, 35, 45, 60, 75, 100, and 150 ppm. The study was originally scheduled as six identical replicates, conducted in six identical rooms, which were loaded sequentially over 10 months in reverse numerical order of room numbers: 146, 145, 144, 143, 142, and 141. Because of low mortality in all rooms and a lower bladder tumor prevalence than expected at the 18-month scheduled killing in the first three replicates (rooms 146, 145, 144), all scheduled killings not yet completed in the last three replicates (rooms 143, 142, 141) were extended to 24 months (728 days) and were not conducted as originally planned (table 1).

In the analysis of liver tumors, only animals for which that organ was histologically examined were included, after all animals for which autolysis precluded a diagnosis of the cause of death had been excluded. Text-figures 1 and 2 display the time-to-tumor ($1-\hat{S}(t)$) and time-to-death ($1-\hat{P}(t)$) curves for the 150-ppm dose groups of rooms 144 and 143, respectively. Note that time to tumor and time to death were accelerated for animals in room 143 when compared to the same parameters for animals in room 144. This is representative of a general tendency in all of the last three replicates (rooms 143, 142, 141) for animals to respond earlier than they did in the first three replicates (rooms 146, 145, 144) [*see* (*16*)]. The estimated median time to liver tumor at 150 ppm in room 144 was 824 versus 728 days in room 143.

The time-to-tumor distribution curve $1-\hat{S}(t)$, which estimates the probability of occurrence of occult liver tumors at any prespecified time t, provides important information not available on time to onset of tumor without assignment of cause of death. Sometimes prevalence estimates obtained from scheduled killing data have been mistakenly used as estimates of the time-to-tumor distribution. In other instances cumulative proportions of animals observed with tumors at specific times, without regard to mode of death, have been incorrectly claimed as estimates of the time-to-

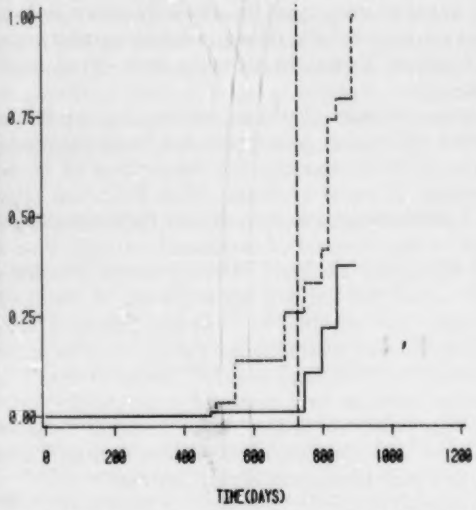
[a] The six replicates are shown by dose and month for the continuous feeding portion of the ED_{01} study. Before alteration of schedules, killings were to have been conducted in all replicates at all times indicated, except that no killings were scheduled originally at 24 mo.

[b] Where no replicates are noted as having been removed, no killings were done.

[c] Killings were conducted at 24 mo for replicates 4, 5, and 6.



TEXT-FIGURE 1.—Time-to-tumor and mortality curves with respect to liver tumors for female BALB/c mice fed 150 ppm 2-FAA (room 144). Dashed step function: $1-\hat{S}(t)$=estimated time-to-onset distribution; solid step function: $1-\hat{P}(t)$=estimated time-to-death distribution; *dashed, vertical line* at 728 days (24-mo killing).

tumor distribution. By properly accounting for mode of removal of an animal, the time-to-tumor curves represented in text-figures 1 and 2 actually estimate the underlying but unspecified time-to-tumor distribution functions. In addition to the direct use of time-to-tumor information, such as in refining risk extrapolation of carcinogenic compounds (*17*), one can use the time separation of $1-\hat{S}(t)$ and $1-\hat{P}(t)$ to arrive at a rough estimate of the time lapse between histologic observability of an internal tumor and the resultant death or morbidity of an animal. From text-figures 1 and 2, an estimate of approximately 5 months (150 days) is obtained for death from liver tumor after onset. Using a parametric procedure, Kodell et al. (*18*) obtained a similar estimate irrespective of dose group.

All animals except those in which autolysis precluded a diagnosis of the cause of death were used in the RCS analysis. Because the histopathologic criteria utilized in this study were those recommended by Dunn (*19*), the various types of lymphoma were excluded from this analysis. An additional study combining RCS with lesions classified as lymphomatous was also done, with the same basic results and conclusions as those reported below for RCS alone.

Text-figures 3 and 4 display time-to-tumor and time-to-death curves for the 150-ppm dose groups of rooms 144 and 143, respectively. The most striking feature of these plots is the large "jump" in the time-to-tumor curve for room 143, in contrast to the time-to-tumor curve for room 144. In fact, the time-to-tumor and time-to-death curves for room 144 stay very close together throughout the animals' lifetimes, whereas for room 143, after the large jump at approximately 728 days (time indicated by a dashed vertical line on all plots), the curves tend to stay apart, although they were nearly coincident until that time. The closeness of $1-\hat{S}(t)$ to $1-\hat{P}(t)$ evident for room 144 was characteristic of all dose groups housed in rooms 146, 145, and 144 (first three replicates). In contrast, the large jump phenomenon at 728

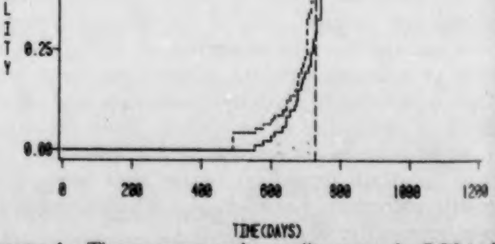
TEXT-FIGURE 3.—Time-to-tumor and mortality curves for RCS in female BALB/c mice fed 150 ppm 2-FAA (room 144). Dashed step function: $1-\hat{S}(t)$=estimated time-to-onset distribution; solid step function: $1-\hat{P}(t)$=estimated time-to-death distribution; *dashed, vertical line* at 728 days (24 mo killing).

days for $1-\hat{S}(t)$ characterized all dose groups of rooms 143, 142, and 141 (last three replicates).

The contradiction in time-to-tumor distributions between the first and last three replicates apparently resulted because throughout the experiment RCS was classified as cause of death more often than was appropriate. Because RCS is a malignant disease, there was a tendency for pathologists to assign it as the cause of death when it was present at necropsy in dead or moribund animals for which no other information was available on which to base the cause of death. Approximately 90% of the RCS which occurred in lifetime groups (i.e., uncontaminated by being killed) was listed as the cause of death. If RCS really were a rapidly lethal disease, then the prevalence, i.e., the proportion of animals with RCS in the live population, would never be very high, and the time-to-tumor and time-to-death curves would lie very close together, as is generally the situation for rooms 146, 145, and 144 (text-fig. 3). This premise can be seen theoretically by observing that prevalence equals $1-S(t)/P(t)$. If the prevalence is very low, then $S(t)$ and $P(t)$ must necessarily be very close to one another, and vice versa. Because in the first three rooms (144–146) there was not a scheduled killing at 24 months, the notion of low RCS prevalence was not contradicted. At the 18-month killing, the prevalence of RCS (a late-occurring disease) was indeed low (e.g., 7/130=5% in controls, room 144).

Whereas in the last three replicates (rooms 141–143) a similar impression of RCS as a rapidly lethal disease with low prevalence was given until 24 months, at the 24-month killing an unexpectedly large prevalence was observed (e.g., 42/103=41% in controls, room 143). Both before and after this time, practically every dead or moribund animal with RCS present was assigned RCS as the cause of death, even though a substantial number of animals without RCS were assigned other causes of death. Because the 24-month killing data reflects a high prevalence of RCS and because causes of death other than RCS were responsible for the death of animals *without* RCS, one would expect that these other causes were also responsible for deaths of some animals *with* RCS. Thus more animals with RCS than were reported to have died of other causes should have died of other causes before dying of RCS. This would have resulted in more incidental and fewer fatal classifications of RCS before and after 24 months, so that the prevalence estimate obtained from dead and moribund animals would then reflect the true high prevalence, if one assumes that the prevalence did not change at approximately 24 months. Thus the 24-month killing data contradicted the impression of the degree of lethality of RCS obtained from data from only dead and moribund animals. In addition, a surprisingly large number of animals killed at 24 months had several organs affected with RCS, which is also inconsistent with the picture of rapid lethality portrayed by virtually every RCS-bearing animal's dying from the disease, whereas a substantial number of non-RCS-bearing animals were dying from other causes.

Thus it appears that one assumption underlying the proposed estimation procedure has been violated in the situation of RCS, namely, the assumption of an accurate designation of cause of death. That RCS was apparently given heavier weight than it should have been is probably related to the removal of moribund animals from experiments by animal handlers, which was the practice so that tissues would not be lost to autolysis. A cause-of-death assignment was required by the data-collection system for all moribund and dead animals, thus forcing the pathologist to "project" a moribund animal's cause of death. If some moribund animals were removed prematurely, i.e., before death was really imminent, then in those situations the pathologist was improperly compelled to assign a cause of death to a live, albeit possibly ill, animal.



TEXT-FIGURE 4.—Time-to-tumor and mortality curves for RCS in female BALB/c mice fed 150 ppm 2-FAA (room 143). Dashed step function: $1-\hat{S}(t)$=estimated time-to-onset distribution; solid step function: $1-\hat{P}(t)$=estimated time-to-death distribution; *dashed, vertical line* at 728 days (24 mo killing).

No such discrepancy between early and late replicates with respect to time to liver tumor was noted (text-figs. 1, 2). The lack of a large jump at 24 months in room 143 at 150 ppm is representative of all dose groups in the last three rooms. This lack of a large jump indicates that the estimated prevalence at the 24-month killing was in line with what was expected on the basis of dead and moribund animal data up to that time. This suggests that cause of death determination was more accurate for liver tumor mortality than for RCS mortality, which is gratifying inasmuch as liver tumor was a dose-related end point of interest. The other principal dose-related end point of interest, bladder carcinoma, exhibited the same consistency in cause-of-death assignment as did liver tumor. Both the liver and bladder tumor data support the applicability of the recommended time-to-tumor estimation procedure. And although the cause-of-death assumption may have been violated in the case of RCS, nevertheless when the recommended procedure was used, it helped demonstrate that RCS is not as rapidly lethal as had been thought. The question remains as to what, if anything, can be done to improve assignment of cause of death in an animal bioassay for carcinogenesis. This question is addressed in the next section.

IMPROVING CAUSE OF DEATH ASSIGNMENT

The assumption of accurate cause-of-death assignment has been required for many statistical analyses of survival data that have appeared in the literature. Thus it is not a new concept in the foregoing estimation of the time-to-tumor distribution, although it is a necessary condition for accurate analysis.

Because scheduled sacrifice data were used for detection of a discrepancy in prevalence estimates of RCS in the present study, one experimental modification would be to schedule more frequent killings, perhaps with only a few animals being killed each time. This schedule would help keep the true prevalence in proper perspective, although it would not affect overdesignation of a particular cause of death.

With the removal of moribund animals in lieu of letting them die, a possible early-removal bias can be introduced. So that the examining pathologist would be allowed more flexibility, a moribund animal should be assigned a cause of *morbidity* rather than a cause of death. In this way the pathologist would not be forced to concur with the animal caretaker who removed the animal that death was imminent.

The pathology system should also incorporate a graded response into cause-of-death and cause-of-morbidity assignments. If the examining pathologist is able to identify a single entity as causing death or morbidity, he should then assign this as the *primary* cause. If more than 1 lesion is determined to be responsible for removal of an animal, then each lesion should be assigned as a *contributing* cause, and no primary cause should be recorded. Finally, lesions that are thought to have had a possible influence on an animal's death or morbidity may be listed as *equivocal* causes. If no condition classifiable as a primary, a contributing, or an equivocal cause of death is found in an animal, then that animal should be classified as having died from an unknown cause.

Distinguishing between primary and contributing causes of death will offer some flexibility to the statistician as well as to the pathologist in the classification of moribund animals with respect to fatal or incidental occurrence of tumors, in the interest of alleviating problems such as those encountered with RCS. For example, in analyzing a particular type of tumor, one might investigate the impact of classifying occurrences of that tumor as fatal only if they are primary causes of death (morbidity) as opposed to treating both primary and contributing causes as fatal.

The introduction of cause of morbidity for moribund animals will not be of direct help to the statistician, who must continue to treat cause of morbidity and cause of death identically in the performance of a time-to-tumor estimation. That is, the statistician must use both cause of death and cause of morbidity as "cause of removal" to distinguish between fatal and incidental tumors. In this sense, for example, a tumor classified as the primary cause of morbidity for a moribund animal would be treated as a fatal tumor in a statistical analysis of time to tumor.

A cause-of-death–cause-of-morbidity system which incorporates the above concepts is being developed at the National Center for Toxicological Research in the spirit of that recommended by the International Agency for Research on Cancer (*11*), although the system at the National Center for Toxicological Research is not identical with the recommendations of the International Agency for Research on Cancer. In the future it will be of interest to evaluate this new system with respect to RCS cause-of-death diagnosis to measure any improvement over the present system.

Murine Lymph Node Natural Killer Cells: Regulatory Mechanisms of Activation or Suppression[1,2,3]

Goro Hisano[4,5] *and* Nabil Hanna[4,6]

ABSTRACT—The kinetics and organ distribution patterns of lymph node natural killer (NK) cell activation or suppression were found to vary according to the type, dose, and route of administration of *Corynebacterium parvum* or polyinosinic-polycytidylic acid (poly I·poly C). Activation of lymph node NK cells by local injections of *C. parvum* into the footpad or the peritoneum was restricted to the regional lymph nodes; contralateral and distant lymph nodes were not involved. This selectivity persisted even though splenic and peripheral blood NK cells were strongly activated by the same treatment. Conversely, poly I·poly C induced systemic activation of NK cells without selectively activating the regional lymph nodes. The decline of NK cell activity observed 2 weeks after *C. parvum* treatment was associated with a state of unresponsiveness to a second injection of NK cell stimulants. The expression of *C. parvum*-induced suppression could be systemic or restricted to the regional lymph nodes. Possible mechanisms for the anatomical compartmentalization of NK cell activation or suppression and the implications for the control of tumor growth and dissemination in vivo are discussed.—JNCI 1982; 69:665–671.

The possible role for NK cells in the in vivo resistance against transplantable lymphomas and nonlymphoma solid tumors has been suggested by several studies (*1–8*). For example, adult nude mice exhibit high NK cell activity and strong resistance against syngeneic, allogeneic, and xenogeneic lymphoma cells (*1, 2, 9*). Furthermore, B16 melanoma cells injected into beige mice, which are known to be deficient in NK cell activity, exhibit shorter induction time, faster growth rate, and higher incidence of experimental and spontaneous metastases (*7, 10*) than those injected into normal syngeneic mice. Several recent studies showed that NK cells play a major role in the destruction of circulating tumor cells (*8, 11*) and in the inhibition of hematogenous metastatic spread (*8*). However, they also showed that NK cells are less effective in destroying tumor cells that have extravasated into the lung parenchyma. Thus regulation of the activity of NK cells within the anatomical compartments to which they are confined is important in the control of tumor growth and dissemination. NK cells have a characteristic organ distribution. The activity of NK cells is highest in peripheral blood, followed in descending order by spleen, lymph nodes, and bone marrow (*12, 13*). The lymph nodes are common sites for spontaneous metastases from local primary tumors. Therefore, the induction and maintenance of high levels of NK cell activity in lymph nodes are biologically and perhaps clinically significant. The use of BRM that activate NK cells and macrophages in the prevention and therapy of lymph node metastases has been described previously (*14, 15*). However, depending on the type, dose, and route of administration of the BRM, augmentation or suppression of NK cell-mediated cytotoxicity may be obtained (*16–18*).

In this study, we investigated the kinetics, regulation, and mode of activation of NK cells in lymph nodes by local or systemic administration of the bacterial adjuvant *C. parvum* and the IFN inducer poly I·poly C. Also, we examined the effect of these BRM on the generation of local or systemic suppression, which may interfere with the reactivation and maintenance of high NK cell activity in lymph nodes.

MATERIALS AND METHODS

Animals.—Specific-pathogen-free (C3H/HeN mammary tumor virus-negative ($C3H^-$) and athymic BALB/c nude mice were obtained from the Animal Production Area, NCI-Frederick Cancer Research Facility, Frederick, Md. Within a single experiment all mice were age and sex matched and were 3–6 weeks old at the beginning of most experiments.

Reagents.—*C. parvum* (7.0 mg/ml; Burroughs Wellcome Co., Research Triangle Park, N.C.) was diluted in PBS before injection. Poly I·poly C (Sigma Chemical Co., St. Louis, Mo.) was prepared in PBS (1.0 mg/ml) and stored at −70°C until use. Mouse fibroblast IFN (10^6 U/ml) was purchased from Calbiochem-Behring Corp., La Jolla, Calif. IFN levels in sera of mice treated with BRM were determined by virus-inhibition assay in vitro (Biofluids Inc., Rockville, Md.).

Tumors.—The YAC-1, a Moloney virus-induced lymphoma of A/Sn origin (*19*), was maintained in culture with CMEM (Flow Laboratories, Rockville, Md.). The cell line was tested and found to be free of mycoplasma.

In vitro assay for NK cell-mediated cytotoxicity.—Mice were killed by cervical dislocation, and their spleen and lymph

nodes (popliteal, inguinal, and mesenteric) were removed. We prepared single cell suspensions by mechanically disrupting the lymphoid organs and forcing them through a 60-mesh wire screen. We dispersed cell aggregates by gentle pipetting and then filtered the cell suspensions through a 200-mesh nylon screen. The red blood cells in the spleen cell preparations were removed by water lysis, and all lymphoid cells were washed and resuspended in CMEM. The final concentration was 5×10^6 cells/ml. For isolation of effector cells from peripheral blood, mice were anesthesized in ether, and blood was drawn by cardiac puncture with the use of 20 U heparin/ml as anticoagulant. The blood was diluted 1:3 in Ca^{2+}-free and Mg^{2+}-free Hanks' balanced salt solution that contained 10 U heparin/ml and layered on Ficoll-metrozoate gradient. After centrifugation at $1{,}000\times g$ for 30 minutes, the cells at the interface were collected, washed, and resuspended in CMEM. Effector cells from 5 mice per group were pooled for the in vitro cytotoxicity assay.

The in vitro NK cell-mediated killing of YAC-1 lymphoma target cells was evaluated by the 4-hour ^{51}Cr release assay. YAC-1 cells (1×10^7/0.2 ml) obtained from cultures in exponential growth phase were incubated with 200 μCi of $Na^{51}CrO_4$ for 1 hour at 37°C. The labeled cells were washed thoroughly and adjusted to a final concentration of 10^5 cells/ml in CMEM. Portions (0.1 ml) of lymphoid effector cell suspension were added to 10^4 radiolabeled YAC-1 lymphoma target cells in U-shaped wells of microtiter plates to yield E:T ratios of 50:1, 25:1, 12:1, and 6:1. The plates were centrifuged at $60\times g$ for 5 minutes and incubated for 4 hours at 37°C in a humidified incubator with 5% CO_2. The amount of ^{51}Cr released into the medium was measured, and percent killing was calculated by the formula: Percent cytotoxicity=$[(E-C)/T]\times 100$, where E=cpm released in the presence of effector cells, C=cpm released by target cells incubated alone in medium, and T=total cpm input per well. The experimental error for triplicate determinations (95% confidence interval) was less than 5% of the mean cytotoxicity, except for cytotoxicity values less than 15% for which it was ±3%.

In several experiments the suppressive effect of treatment with *C. parvum* on activation of NK cells was studied. Percent suppression was calculated according to the formula: Percent suppression = $1 - [(A - B)/(C - D)] \times 100$, where group A received one injection 14 days before testing and a second injection 3 days before testing, groups B and C received single injections at 14 or 3 days before testing, respectively, and group D served as untreated control. The responses were expressed in LU per 10^7 lymphoid effector cells, which were calculated from the linear parts of the cytotoxicity curves. In most cases the number of lymphoid cells that killed 10% (LU_{10}) or 20% (LU_{20}) of the labeled target cells constituted 1 LU. In instances in which NK cell-mediated cytotoxicity was very low (e.g., unstimulated lymph node cells), the least-squares linear fit was calculated and the lines were extrapolated.

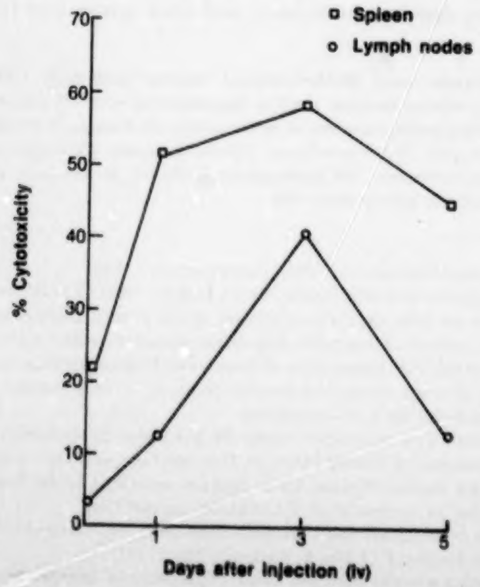
Statistical analysis—Student's *t*-test was used.

RESULTS

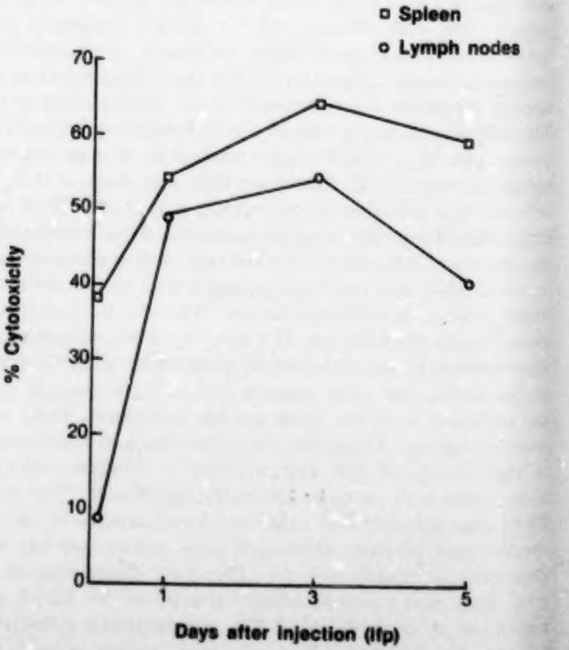
Kinetics of Activation of Lymph Node NK Cells

Lymphoid cells from popliteal, inguinal, and mesenteric lymph nodes of normal or *C. parvum*-treated mice were tested for NK cell activity against YAC-1 lymphoma target cells in a 4-hour ^{51}Cr release assay.

In 22 separate experiments, the levels of NK cell activity



TEXT-FIGURE 1.—Kinetics of NK cell activation in spleen and popliteal lymph nodes after iv injection of *C. parvum* (160 μg/mouse) into 6-wk-old C3H$^-$ mice. Percent cytotoxicity was at an E:T ratio of 50:1.



TEXT-FIGURE 2.—Kinetics of NK cell activation in spleen and lymph nodes after ifp injection of *C. parvum* (10 μg/mouse) into 6-wk-old C3H$^-$ mice. Percent cytotoxicity was at an E:T ratio of 50:1.

in lymph nodes of normal 4- to 12-week-old C3H⁻ mice averaged 5.2±3.0% cytotoxicity (range, 2.0–11.8%) at an E:T ratio of 50:1. In the same experiments, spleen cells exhibited higher levels of cytotoxic activity, with a mean of 29.4±8.0% (range, 20.1–52.7%). The activity of both splenic and popliteal lymph node NK cells could be boosted by systemic (iv) or local (ifp) injections of *C. parvum* (text-figs. 1, 2). Although the activity of spleen and lymph node NK cells reached a peak on day 3 after injection, the route of administration of *C. parvum* significantly affected the onset and decline of the natural cytotoxicity. Thus following iv injection of *C. parvum*, we observed only a slight activation of popliteal lymph node cells 24 hours after treatment, a peak response on day 3, and a sharp decline to pretreatment levels by day 5 (text-fig. 1). In contrast, ifp injection of *C. parvum* caused a marked activation of NK cells in regional (popliteal) lymph nodes 24 hours after treatment, and high levels of activity were maintained through day 5 after treatment (text-fig. 2). Two weeks after *C. parvum* injection, the NK cell activity in the spleen and popliteal lymph nodes was four times higher in mice given ifp injections than in those given iv injections or in normal controls. (*See* tables 3, 4.)

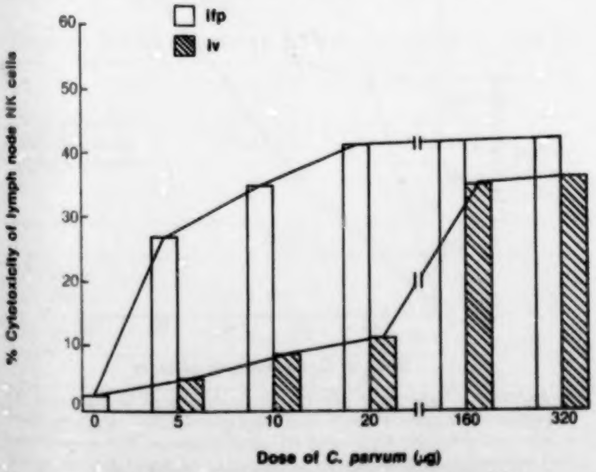
The optimal doses of *C. parvum* that activate NK cells in popliteal lymph nodes were found to be highly dependent on the route of administration (text-fig. 3). A marked activation of NK cells was observed 3 days after ifp injection of as little as 5 μg of *C. parvum*, and maximum activity was obtained with 20 μg of adjuvant. In contrast, for optimal activation of lymph node NK cells by the iv route, large doses of *C. parvum* (160–320 μg/mouse) were required.

The quantitative evaluation of NK cell activation and suppression can be affected by the adjuvant-induced alterations in the cellularity of the lymph nodes and spleen. For example, after iv injection of large doses (160 μg) of *C. parvum*, an increase in the number of cells in the popliteal lymph nodes was observed on day 3 (3.1 times that of untreated controls); this subsided to pretreatment levels by day 14 post injection. The same treatment, however, led to a marked splenomegaly, which was most pronounced 14 days after treatment (yield of 150×10^6 cells as compared to 50×10^6 cells/spleen in untreated mice). Conversely, the ifp injection of as little as 10 μg of *C. parvum* led to a marked increase in the number of cells in the regional popliteal lymph nodes by day 3 after injection (4–7 times that of untreated controls) and reached maximal levels by day 14 (6–10 times that of normal lymph nodes). The same treatment had only a modest effect on the cellularity of the spleen. The increase in the number of spleen cells was dose-dependent and ranged from 1.1 to 2.2 times that of untreated controls.

Dependence of Organ Selectivity of NK Cell Activation on Route of *C. parvum* Administration

Using 3- to 4-week-old C3H⁻ mice with initially low NK cell activity, we next studied the anatomical compartmentalization of NK cell activation following iv, ip, or ifp injection of *C. parvum*. The data presented in table 1 show that ifp injection of 10 μg of *C. parvum* markedly activated NK cells in the regional popliteal lymph nodes, spleen, and peripheral blood. In contrast, no activation of NK cells in the contralateral popliteal lymph nodes or mesenteric lymph nodes and only a moderate stimulation in the regional inguinal lymph nodes could be detected. Doses up to 160 μg of *C. parvum* administered ifp also failed to activate NK cells in the contralateral popliteal lymph nodes, even though NK cells in the spleen and peripheral blood were highly activated (data not shown).

A different pattern of activation was observed after the ip injection of 10 μg of adjuvant. Whereas NK cells in the spleen and peripheral blood were highly activated on day 3 after adjuvant treatment, NK cells in the popliteal lymph



TEXT-FIGURE 3.—Effect of dose and route of administration of *C. parvum* on activation of lymph node NK cells. Cytotoxicity of popliteal lymph node cells was assessed 3 days after ifp or iv injections of *C. parvum* into 6-wk-old C3H⁻ mice. Percent killing was at an E:T ratio of 50:1.

Peripheral blood	8.4	41.9	55.8			

[a] NK cell-mediated killing was measured 3 days after *C. parvum* injection into 3- or 4-wk-old C3H⁻ mice. Each treatment group contained 5 mice.

[b] Lymph nodes from both sides were pooled.

[c] Regional lymph nodes only.

nodes were not activated, and NK cells in the inguinal and mesenteric lymph nodes were only moderately stimulated. These patterns of organ selectivity were found to be unchanged at days 5, 8, and 11 after ip or ifp injection of *C. parvum*. Although iv administration of *C. parvum* activated NK cells in the spleen and the mesenteric and popliteal lymph nodes, the activation of the NK cells in the popliteal lymph nodes required relatively high doses of the adjuvant (table 1, expt II). Moreover, under optimal stimulation conditions, the overall NK cell activity generated in mesenteric lymph nodes was consistently lower than that detected in popliteal lymph nodes. Thus both the route of injection and the dose of *C. parvum* affect the levels and the organ localization of activated NK cells.

Generalized Activation of Lymph Node NK Cells by Poly I•Poly C

Since IFN plays a significant role in the regulation of NK cell activity, the levels of IFN produced by different BRM may influence the activation of NK cells at different sites. Thus we investigated the pattern of NK cell activation after the injection of poly I·poly C, a potent IFN inducer and NK cell activator (*20*). The range of IFN levels in the blood 16 hours after injection of poly I·poly C or *C. parvum* was 500–1,580 and 5–20 IU/ml, respectively. The results (table 2) clearly demonstrate that organ selectivity or site restriction of NK cell activation did not occur after local poly I·poly C injection. Thus unlike *C. parvum*, ifp injection of poly I·poly C activated NK cells in the regional as well as the contralateral popliteal lymph nodes. Moreover, NK cell activity in popliteal lymph nodes was enhanced also when poly I·poly C was administered ip.

Suppression of NK Cell Activity in Spleen and Lymph Nodes

The iv injection of large doses of *C. parvum* induces severe and long-lasting suppression of spleen NK cell activity that occurs after the early and transient activation period (*16*). In the following experiments, we investigated whether the *C. parvum*-induced suppression of NK cell activation is confined to the spleen or is generated also in lymph nodes and whether the suppression is influenced by the dose and route of adjuvant administration. Groups of mice were given iv injections of 10–160 μg of *C. parvum*; 11 days later, they were given a second iv injection of 160 μg of the adjuvant; 3 days later, NK cell-mediated cytotoxicity in spleen and lymph nodes was monitored in vitro. The results (table 3) show that an initial treatment with 160 μg of *C. parvum* markedly suppressed the ability of a second injection of the same adjuvant to activate NK cells in the spleen and lymph nodes. Similarly, NK cells were not reactivated when poly I·poly C was injected into mice initially treated iv with large doses of *C. parvum* (table 3). Although the degree of suppression of NK cell activation was dependent on the dose of *C. parvum* used in the initial treatment, at lower doses the suppression was more pronounced in the spleen than in the lymph nodes (text-fig. 4).

[*] NK cell-mediated killing was measured 1 day after poly I·poly C injection into 5-wk-old C3H⁻ mice.

We then examined the systemic and/or local suppression of NK cell-mediated cytotoxicity induced by ifp injection of *C. parvum*. Mice were inoculated with 10 or 160 μg of *C. parvum* into one hind footpad. Eleven days later, the animals received a second iv injection of 160 μg of adjuvant. NK cell-mediated cytotoxicity in the spleen and regional and contralateral popliteal lymph nodes was assayed in vitro 3

TABLE 3.—C. parvum-*induced suppression of NK cell activation*

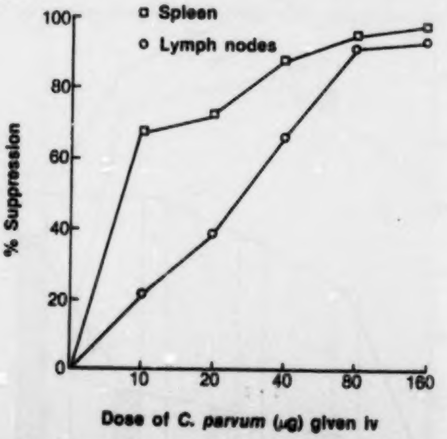
[a] 6-wk-old C3H⁻ mice were given iv injections of 160 μg *C. parvum* or 10 μg poly I·poly C.

[b] NK cell cytotoxicity was tested in vitro on day 14. *Numbers in parentheses* are percentages of inhibition of NK cell activation.



TEXT-FIGURE 4.—Suppressive effects of iv injections of *C. parvum* on the activation of NK cells in lymph nodes and spleen. C3H⁻ mice were given iv injections of 10, 20, 40, 80, and 160 μg of *C. parvum*. Eleven days later, they received an iv challenge of 160 μg of *C. parvum*; 3 days later, NK cell-mediated cytotoxicity was assayed. Percent suppression was calculated as described in "Materials and Methods." The differences in percent suppression of spleen vs. lymph node NK cell activity observed with doses of 10 and 20 μg *C. parvum* were highly significant ($P<0.001$).

days after the iv challenge. The results (table 4) indicate that, unlike the generalized suppression observed following iv injection of *C. parvum*, NK cell suppression initiated by ifp injection of *C. parvum* was confined to the regional lymph nodes draining the site of inoculation. Thus ifp injection of 10-160 µg of *C. parvum* abrogated the response of NK cells in the regional popliteal lymph node, but not in the contralateral lymph node or spleen, to a second injection of *C. parvum* administered 11 days later. Local suppression of NK cell activity in the regional lymph nodes, but not in the spleen, also was detected when the second challenge with *C. parvum* was given into the same footpad rather than systemically (data not shown).

In Vitro Activation of Lymph Node NK Cells by Poly I•Poly C and IFN

We have demonstrated that activation and suppression of NK cells by local injections of *C. parvum* are compartmentalized and display restricted organ distribution patterns. To delineate further this phenomenon, we investigated whether lymph nodes from normal untreated mice contain cells that could be activated in vitro by IFN and IFN inducers. Under such in vitro conditions, the problems of in vivo recruitment and redistribution of activated cytotoxic cells are bypassed. Thus lymphoid cells pooled from popliteal, inguinal, axillary, and submandibular lymph nodes were incubated in vitro with either 0.5 µg poly I·poly C/ml for 24 hours or 500 U IFN/ml for 2 hours. The data shown in table 5 demonstrate that a brief incubation with IFN enhanced NK cell-mediated cytotoxicity in both spleen and lymph node cell preparations. Similarly, a 24-hour incubation with poly I·poly C activated lymph node NK cells, but only after the addition of 1-2% peritoneal adherent cells at the initiation of the incubation period (table 5). Quantitatively, the levels of NK cell-mediated cytotoxicity detected after in vivo or in vitro activation were uniformly higher in the spleen than in the lymph nodes.

[a] Resident peritoneal cells were harvested from normal C3H⁻ mice, and 2×10^5 adherent cells were added to the cultures as indicated.

[b] Lymph node or spleen cells (10^7 cells/well) obtained from 5-wk-old C3H⁻ mice were incubated with 0.5 µg poly I·poly C/well or 500 U IFN/well for 24 and 2 hr, respectively.

DISCUSSION

Our findings demonstrate that activation or suppression of NK cells could be systemic or restricted to certain anatomical compartments, depending on the type, dose, and route of administration of the BRM. Also, the onset and/or duration of NK cell activation is affected primarily by the route of injection of the activating agent. Thus low doses of *C. parvum* injected into the footpad were highly effective in activating NK cells in the regional lymph nodes, spleen, and peripheral blood, but they failed to activate NK cells in mesenteric or contralateral popliteal lymph nodes. In contrast, when *C. parvum* was administered iv, large doses were required to activate lymph node NK cells, and the activity persisted for a much shorter time than activity induced by local ifp injection. At lower doses of *C. parvum*, NK cells were selectively activated in the spleen and peripheral blood, but not in popliteal lymph nodes. Similarly, ip injection of *C. parvum* activated NK cells in the spleen, peripheral blood, and mesenteric and inguinal lymph nodes but not in popliteal lymph nodes.

This result is in agreement with some (*21, 22*), but not all (*16*), recent reports that demonstrated successful activation of spleen NK cells after ip injection of bacterial adjuvants. Such discrepancies may be attributed to differences in the strain or age of the mice used. The anatomical compartmentalization of NK cell activation suggests that the evaluation of NK cell-mediated cytotoxicity at one site (spleen or peripheral blood) does not necessarily reflect activity at a different location (lymph nodes). Moreover, the absence of detectable NK cell activation in lymph nodes, despite the strong activation of peripheral blood NK cells, suggests that circulating activated NK cells do not migrate freely into normal, unstimulated lymph nodes. This is not surprising since recent studies have shown that activated NK cells differ from their naive counterparts in several characteristics (*23*). Thus activation of lymph node NK cells with *C. parvum* probably requires it to be delivered, perhaps within macrophages, to the site of activation where local production of small amounts of IFN is sufficient to activate NK cells in situ. This conclusion is substantiated by our observation of dose-dependent differences in NK cell activation in the popliteal lymph nodes induced by ifp or iv administration of *C. parvum* (text-fig. 3). Further evidence that the low blood levels of IFN induced by *C. parvum* treatment may be the limiting factor in attaining a generalized activation of NK cells is provided by the findings that local ifp injections of potent IFN inducers, such as poly I·poly C, activate NK cells in the regional as well as the contralateral lymph nodes. Thus when high blood levels of IFN were achieved, a more generalized activation of NK cells was observed without site restriction, such as restriction to the regional draining lymph nodes.

Recent evidence has indicated that stimulation of NK cell-mediated cytotoxicity by IFN involves the activation of precursors of NK cells and their maturation into highly cytotoxic effectors (*24, 25*). Therefore, in situ activation of NK cells in lymph nodes requires that such NK cell precursors be present at or recruited to the site of activation. Indeed, the natural cytotoxic activity of lymphoid cells from normal, unstimulated lymph nodes may be boosted in vitro by IFN or poly I·poly C. However, poly I·poly C-induced activation of lymph node NK cells in vitro required the addition of 1–2% normal peritoneal adherent cells. This finding agrees with that of previous studies showing that removal of macrophages inhibits the activation of NK cells by poly I·poly C but not by IFN (*26*). Although these experiments demonstrate that precursors of NK cells exist as a normal cellular constituent of unstimulated lymph nodes, they do not rule out that local injection of BRM such as *C. parvum* may recruit unactivated NK cells and/or their precursors together with accessory cells to the local draining lymph nodes. The hypercellularity observed in draining lymph nodes as early as 3 days after *C. parvum* injection suggests that local NK cell recruitment could be a significant component of the host response.

Recent studies have indicated that macrophages are required for stimulation of NK cell activity by BRM (*26–28*) and for the maintenance of normal levels of natural cytotoxicity in vivo (*26*). However, following activation with reticuloendothelial system stimulants, macrophages were found, although not invariably (*17*), to suppress the lytic activity of NK cells (*18*). Our findings indicate that the decline of NK cell activity that follows the early and transient activation by *C. parvum* is associated with a state of resistance to reactivation by the same or other unrelated NK cell stimulants. For example, an optimal challenge with *C. parvum* or poly I·poly C failed to boost NK cell activity in recipients treated 2 weeks earlier with an iv injection of *C. parvum*. Whereas low doses were sufficient to suppress selectively spleen NK cell reactivity, larger doses of *C. parvum* also induced suppression in lymph nodes. In contrast, local ifp injection of *C. parvum* inhibited the reactivation of NK cells in the draining lymph nodes without affecting the subsequent responsiveness of the spleen and the contralateral lymph nodes.

Although the suppressive mechanism may be mediated by suppressor cells, such as activated macrophages, it is clear that these cells do not migrate freely into all lymphoid organs. The possibility that site-specific utilization or depletion of NK cells and/or their precursors by the first adjuvant injection might be responsible for the inhibition of subsequent NK cell activation seems very remote, since nylon wool-purified lymph node cells obtained from "suppressed" *C. parvum*-treated mice could be activated in vitro with IFN (Hisano G: Unpublished observation). Dilution of NK cells by unrelated noncytotoxic cells recruited to the enlarged spleen or lymph nodes by *C. parvum* injection does not seem to contribute significantly to the observed suppression. For example, the number of lymphoid cells recovered from unresponsive popliteal lymph nodes 2 weeks after ifp injection of adjuvant was only 1.3 times higher than that found in lymph nodes at the peak of NK cell response (day 3). Also, large doses of *C. parvum* administered iv markedly suppressed the subsequent activation of lymph node NK cells without increasing the total number of cells per lymph node. However, it could not be ruled out that *C. parvum*-induced histologic alteration in lymph node structure may also contribute to the suppressed response.

In any event, the type and route of administration of NK cell stimulants are important for achievement and maintenance of high levels of NK cell activity at specific lymph nodes. Moreover, the possible generation of long-lasting local or systemic suppression of NK cells indicates that multiple injections of BRM are not necessarily effective in maintaining the high levels of NK cell activity required for the control of tumor cell growth and dissemination.

Androgen Control of Cytosol Progesterone Receptor Levels in the MT-W9B Transplantable Mammary Tumor in the Rat[1,2,3]

Margot M. Ip,[4] **Richard J. Milholland,**[4] **Untae Kim,**[5] *and* **Fred Rosen**[4,6]

ABSTRACT—The effect of androgen on the levels of the cytosol progesterone receptor was examined in the transplantable rat mammary tumor MT-W9B and in the normal uteri of inbred WF rats. Progesterone receptor levels were barely detectable in tumors grown in male WF rats but were increased after castration or administration of 17β-estradiol. Both effects were blocked by testosterone. In tumors grown in intact female rats, both testosterone and dihydrotestosterone decreased progesterone receptor levels in a dose-dependent manner, and testosterone completely blocked the estradiol-induced increase in progesterone receptor levels in tumors from ovariectomized rats. The inhibitory effect of testosterone in female rats was blocked by the antiandrogen flutamide, suggesting an androgen receptor-dependent mechanism. Neither dihydrotestosterone nor testosterone had any effect on basal levels of progesterone receptor in tumors from ovariectomized rats. In uterus, up to 5 mg dihydrotestosterone/kg did not affect progesterone receptor levels, and a dose of 5 mg/kg was also uterotropic. This fact plus the finding that testosterone only partially blocked the estradiol-induced increase in uterine progesterone receptor levels suggested stimulation of different cell types by testosterone and estradiol. This did not appear to be the case in the tumor, however. Androgen is suggested to act as a negative modulator of progesterone receptor levels, which might have clinical relevance in terms of hormone therapy of breast cancer.—JNCI 1982; 69:673–681.

Androgens were shown to be effective in the treatment of many cases of human breast cancer (*1*); however, the mechanism by which this occurs is still not understood. On the basis of studies in animal model systems, such as the DMBA-induced mammary tumor in rats, several possibilities have been proposed to account for androgen-induced tumor regression. Quadri et al. (*2*) found, for example, that although prolactin secretion was not decreased after the administration of androgens, the administration of prolactin concurrently with androgen could overcome the inhibitory effect. They suggested that androgen might be acting by blocking the peripheral ability of prolactin to promote mammary tumor growth. In agreement with this concept is the finding of Costlow et al. (*3*) that androgen-induced tumor regression was accompanied by a decrease in the level of prolactin receptors in the tumor, although this decrease was not thought to be sufficient to account for the regression. Also, androgen administration decreases estrogen receptor levels in regressing DMBA-induced mammary tumors (*4*), thereby possibly resulting in a decreased sensitivity to estrogen in this estrogen-dependent tumor.

In addition to inhibitory effects of androgen on tumor growth, stimulatory effects have also been observed (*5–7*), which instills concern in regard to patient treatment. Approximately 30% of human breast cancers contain the androgen receptor (*8*); so they are potentially sensitive to the stimulatory effects of androgens via an androgen receptor-dependent mechanism. Androgen receptors have also been demonstrated to be present in several rodent mammary tumors (9–11); at least one of these, the Shionogi mammary tumor, has been shown to be androgen dependent (*10*). Biphasic effects of androgens on the growth of the 7,12-dimethylbenz[*a*]anthracene-induced mammary tumor and the transplantable mammary tumor MT-W9A have also been demonstrated (*5, 12*). The stimulatory effect observed at very high doses may occur via an estrogen receptor-dependent mechanism, since at these concentrations androgens have been shown to cause nuclear translocation of the estrogen receptor in several systems including the 7,12-dimethylbenz[*a*]anthracene-induced mammary tumor (*13, 14*), the human breast cancer cell line MCF-7 (*7*), and the rat uterus (*15–19*). That this translocation is functional is evidenced by an increased synthesis of estrogen-dependent proteins, including the induced protein of uterus and the progesterone receptor (*7, 13, 16, 18, 20, 21*).

Our interest in this topic arose from preliminary observations that suggested that in contrast to the situation observed with estrogen-dependent tissues and tumors, both physiologic and pharmacologic doses of androgens appeared to decrease progesterone receptor levels in the estrogen-independent mammary tumor MT-W9B (*22*). This tumor is considered estrogen independent by virtue of its growth in both male and female syngeneic WF rats and by lack of effect on its growth rate by ovariectomy or hypophysectomy (*23*). Receptors for androgen (*9*), estrogen (*24*), progesterone (*24*), and dexamethasone (Ip MM, Milholland RJ, Rosen F: Unpublished observations) are present in the tumor and, despite the lack of effect of estrogen on growth, estrogen is involved in regulation of progesterone receptor levels (*24*). Tumor regression was not observed in response to pharmacologic doses of either androgen (*9*) or estrogen (*24*). Since estrogen regulation of progesterone receptor levels has been reported in many systems (normal tissues as well as tumors) (*25–30*), we thought it important to further clarify androgen effects on the progesterone receptor and in particular to examine androgen–estrogen interactions in this regard.

MATERIALS AND METHODS

Animals and tumors.—The MT-W9B mammary tumor (*23*)

was transplanted by trocar into 8- to 10-week-old inbred male (200–250 g) or female (140–160 g) WF rats (M.A. Bioproducts, Walkersville, Md.) and became palpable in about 3–3.5 weeks. All rats were maintained in temperature-controlled rooms with a 12-hour light–12-hour dark schedule and were fed ad libitum Teklad rat chow (Teklad Inc., Madison, Wis.) and water. Gonadectomies were performed under pentobarbital sodium anesthesia in our laboratory at various times after tumor transplant. The exact details for each experiment are given in the appropriate table, text-figure, or figure legend.

Reagents.—[1,2,6,7-^{3}H]progesterone (110 Ci/mmol) was purchased from Amersham/Searle Corp., Arlington Heights, Ill. All unlabeled steroids were obtained from Sigma Chemical Co., St. Louis, Mo. Flutamide was a gift of Dr. Arthur Watnick, Schering Corp., Bloomfield, N.J. Dextran-coated charcoal was prepared as described previously (*9*). The scintillation fluid 3a70 was a product of Research Products International Corp., Elk Grove Village, Ill.

Receptor assays.—Cytosol was prepared and stripped of endogenous steroids as described in (*9*). Binding of [^{3}H]-progesterone to tumor cytosol was measured by incubation of 75 µl charcoal-treated cytosol with 5 µl [^{3}H]progesterone (final assay concentration, 20 n*M*) or 5 µl [^{3}H]progesterone containing a hundredfold-molar excess of unlabeled progesterone for 2 hours at 4°C in conical Microtiter plates. We also added a thousandfold-molar excess of hydrocortisone to all incubations to correct for binding of progesterone to the hydrocortisone-binding globulin. At the end of the incubation, bound steroid was separated from free by the addition of 25 µl of a suspension of 5% charcoal–0.5% dextran directly to the Microtiter plate. This incubation mixture with charcoal–dextran was allowed to stand for 2 minutes and then was centrifuged at 850×*g* for 10 minutes, and 75 µl of the supernatant was counted. We made radioactivity measurements in 5 ml scintillation fluid by means of a Beckman LS-100C or LS-150 liquid scintillation counter. Counting efficiency for ^{3}H averaged 40–45%. Specific binding was defined as the difference between total binding and binding in the presence of a hundredfold-molar excess of unlabeled progesterone. Protein in the cytosol was determined according to the procedure of Lowry et al. (*31*).

Statistics—The significance of the difference between two means was evaluated on the basis of Student's *t*-test.

RESULTS

Progesterone receptor levels in tumors grown in male or female rats.—As can be seen in table 1, progesterone receptor levels were near the lower limit of detection in tumors grown in male rats; however, substantial quantities were present in tumors from female rats. Tumors grew well in both male and female rats but were slightly larger ($P<0.02$) in males at the time the rats were killed (table 1).

Estrogen and androgen interactions on progesterone receptor levels in tumors grown in male rats.—To help elucidate the hormonal regulation of progesterone receptor levels in tumors grown in male or female rats, we did an experiment to determine if the progesterone receptor could be induced by estrogen in tumors grown in male rats, and if so, if the effect could be blocked by the concurrent administration of androgen. Text-figure 1 shows that administration of estradiol benzoate at a dose of 25 µg/kg body weight caused a substantial increase in progesterone receptor levels in tumors from both intact and castrated rats. Castration in rats also caused an increase in tumor progesterone receptor levels—a fivefold increase, which was blocked by the administration of 5 mg testosterone propionate/kg (text-fig. 1). Testosterone propionate at the same dose also completely blocked the 17β-estradiol-stimulated enhancement of progesterone receptor levels (text-fig. 1). None of these treatments had any signif-

TABLE 1.—*Effect of sex on tumor progesterone receptor and tumor weight*[a]

Sex	Progesterone receptor, fmol/mg protein	Tumor wt, g
Male	16.7±7.1	4.44±0.51
Female	288±38[b]	2.37±0.53[c]

[a] MT-W9B tumor was transplanted into either male or female WF rats, and rats were killed 42 days later. Values are means ± SEM of 10 rats/group.

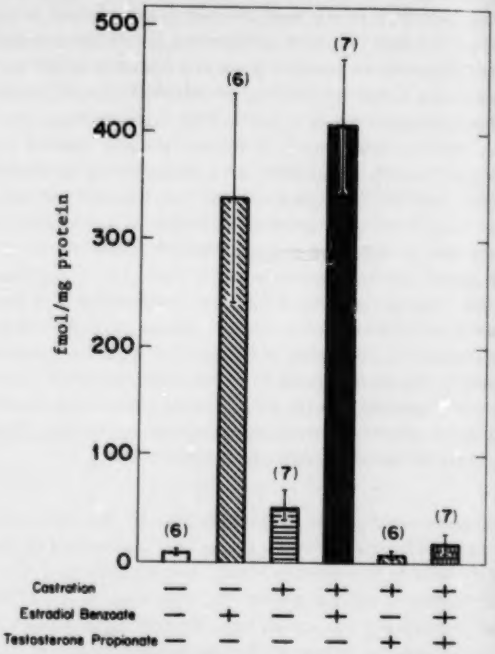
[c] Statistically different ($P<0.02$) compared to male.



TEXT-FIGURE 1.—Effect of castration, estradiol benzoate, and testosterone propionate on progesterone receptor levels in the MT-W9B tumor grown in WF male rats. Rats were castrated or sham castrated 27 days after tumor transplant, and injections of estradiol benzoate (25 µg/kg), testosterone propionate (5 mg/kg), or the corn oil vehicle were initiated 28 days after transplant. Injections were given sc five times/wk. Rats were killed 24 hr after the last injection, 37 days after transplant (seven total injections). *Each bar* represents mean ± SEM. Number of rats/group is shown *in parentheses*. Statistical significance: intact vs. intact + estradiol benzoate, $P<0.01$; intact vs. castrated, $P<0.01$; castrated vs. castrated + estradiol benzoate, $P<0.01$; castrated vs. castrated + testosterone propionate, $P<0.02$; castrated + estradiol benzoate vs. castrated + estradiol benzoate + testosterone propionate, $P<0.01$. Treatment or lack thereof is indicated by *plus* or *minus signs*, respectively.

TABLE 2.—*Effect of castration, estradiol benzoate, and testosterone propionate on tumor and seminal vesicle weight*[a]

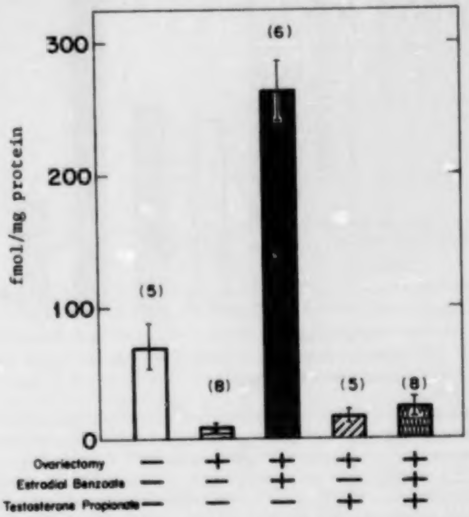
Rat group	Tumor wt, g	Seminal vesicle wt, g
Sham castrated	2.08±0.43	0.82±0.02
Sham castrated + estradiol benzoate	2.43±0.39	0.30±0.02
Castrated	1.36±0.36	0.20±0.01
Castrated + estradiol benzoate	1.89±0.16	0.29±0.03
Castrated + testosterone	2.21±0.15	1.65±0.21
Castrated + estradiol benzoate + testosterone	1.55±0.18	1.74±0.11

[a] These data are from the experiment described in the legend to text-fig. 1. Values are means ± SEM. Statistical significance of the data is as follows—none of the tumor wt are significantly different; for the seminal vesicles: intact vs. intact + estradiol benzoate, $P<0.01$; intact vs. castrated, $P<0.01$; castrated vs. castrated + estradiol benzoate, $P<0.02$; castrated vs. castrated + testosterone propionate, $P<0.01$; castrated + estradiol benzoate vs. castrated + estradiol benzoate + testosterone propionate, not significant.

icant effect on tumor growth (table 2), although a tendency was seen for the tumor to be smaller in untreated castrated rats than in intact controls. We have observed that a longer period of castration than that used in this experiment does significantly retard growth of this tumor in male rats (Ip MM, Milholland RJ: Unpublished observations). Seminal vesicle weights are also presented in table 2 as an index of the effectiveness of the hormonal manipulations.

Estrogen and androgen interactions on progesterone receptor levels in tumors grown in female rats.—The data from the male rats suggested that testosterone could be a physiologic negative modulator of progesterone receptor levels; we were interested to determine if testosterone would also exhibit an inhibitory influence in tumors grown in female rats. Text-figure 2 shows that this was the case. As previously described (*24*), progesterone receptor levels were decreased by ovariectomy and induced by the administration of 17*β*-estradiol to ovariectomized rats; however, this increase was blocked by concurrent administration of testosterone propionate. Testosterone propionate alone at 5 mg/kg had no significant effect on progesterone receptor levels in tumors from ovariectomized rats (text-fig. 2). None of the treatments had any effect on tumor growth (table 3); however, it is interesting that testosterone propionate (5 mg/kg) increased the weight of the uterus from these ovariectomized rats to the same extent as did 25 µg estradiol benzoate/kg. Also, the combination of estradiol and testosterone was more uterotropic than either hormone administered alone.

Estrogen and androgen interactions on progesterone receptor levels in uterus.—In the preceding experiment testosterone appeared to be acting as an antiestrogen in terms of its effect on progesterone receptor levels in the tumor and as an estrogen in terms of its effect on uterine growth. Thus we measured progesterone receptor levels in the uterus of the same animals (text-fig. 3). When the data were expressed as femtomoles per milligram protein (text-fig. 3A), ovariectomy showed no effect on progesterone receptor levels; however, 17*β*-estradiol administration to ovariectomized rats caused a significant stimulation. This was not blocked by concurrent administration of testosterone propionate, but the administration of testosterone propionate alone to ovariectomized rats significantly decreased uterine progesterone receptor levels ($P<0.02$). When the data were expressed as femtomoles per uterus (text-fig. 3B), ovariectomy significantly decreased the total progesterone receptor content of the uterus, whereas both 17*β*-estradiol and testosterone independently caused a significant increase (eightfold and twofold, respectively). Testosterone administration concurrently with 17*β*-estradiol only slightly blocked the stimula-



TEXT-FIGURE 2.—Effect of ovariectomy, estradiol benzoate, and testosterone propionate on progesterone receptor levels in the MT-W9B tumor grown in WF female rats. Rats were ovariectomized or sham ovariectomized 38 days after tumor transplant, and injections of estradiol benzoate (25 µg/kg), testosterone propionate (5 mg/kg), or the corn oil vehicle were initiated 39 days after transplant. Injections were given sc five times/wk. Rats were killed 24 hr after the last injection, 52 days after transplant (nine total injections). Statistical significance: intact vs. ovariectomized, $P<0.01$; ovariectomized vs. ovariectomized + estradiol benzoate, $P<0.01$; ovariectomized vs. ovariectomized + testosterone propionate, not significant; ovariectomized + estradiol benzoate vs. ovariectomized + estradiol benzoate + testosterone propionate, $P<0.01$. tory effect of 17β-estradiol. The apparent discrepancy between the effects of testosterone alone on progesterone receptor levels when expressed as femtomoles per milligram protein and as femtomoles per uterus basis (decrease and increase, respectively) is due to the uterine weight being more than doubled as a result of this treatment (2.5-fold increase; table 3) and the uterine protein concentration being slightly increased (1.5-fold) after treatment.[7]

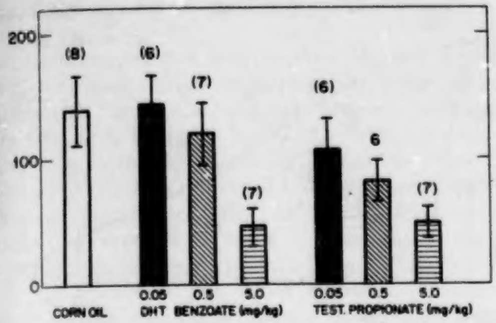
Effect of varying doses of dihydrotestosterone benzoate and testpsterone propionate on progesterone receptor levels in the MT-W9B tumor and in uterus from intact rats.—In addition to examining the effect of testosterone in ovariectomized rats, we also tested the effect of testosterone in intact rats and compared the effect of dihydrotestosterone, the active metabolite of testosterone in many tissues, with that of testosterone. Text-figure 4 shows a comparison of the dose-response relationship between dihydrotestosterone benzoate and testosterone propionate on progesterone receptor levels in the tumor. Both dihydrotestosterone and testosterone were equally effective in reducing tumor progesterone receptor levels. The response appeared to be dose related, although only the dose of 5 mg/kg was statistically significant. In other experiments (text-fig. 5 and data not shown), 0.5 mg testosterone propionate/kg did cause a significant decrease in progesterone receptor levels in the tumor. Increase in the dose of testosterone propionate to 50 mg/kg did not have any further effect on progesterone receptor levels beyond that seen with 5 mg/kg (data not shown). Tumor weights were not significantly affected by dihydrotestosterone or testosterone in the experiment described in text-figure 4 or by doses of 0.05, 0.5, or 5.0 mg dihydrotestosterone benzoate/kg in ovariectomized rats (data not shown). In addition, dihydrotestosterone benzoate, at the same three doses noted in the legend to text-figure 4, had no effect on progesterone receptor levels in tumors from ovariectomized rats (data not shown).

In uterus, increasing doses of dihydrotestosterone benzoate had no effect on progesterone receptor levels when expressed on the basis of femtomoles per milligram protein (text-fig. 6A). On the basis of femtomoles per uterus, the highest dose resulted in an approximate 50% decrease in progesterone receptor levels, reflecting the similar decrease in uterine weight (text-fig. 6B). The same three doses of dihydrotestosterone benzoate had no effect on uterine weight in ovariectomized rats (data not shown). In contrast to dihydrotestosterone benzoate, testosterone propionate showed a dose-dependent decrease in progesterone receptor levels in uterus from intact rats when results were expressed as femtomoles per milligram protein. On the basis of femtomoles per uterus, progesterone receptor levels were decreased by both doses at 0.5 and 5 mg/kg; however, the decrease at dose 5 mg/kg was not as remarkable because this dose also doubled the size of the uterus (text-fig. 6B).

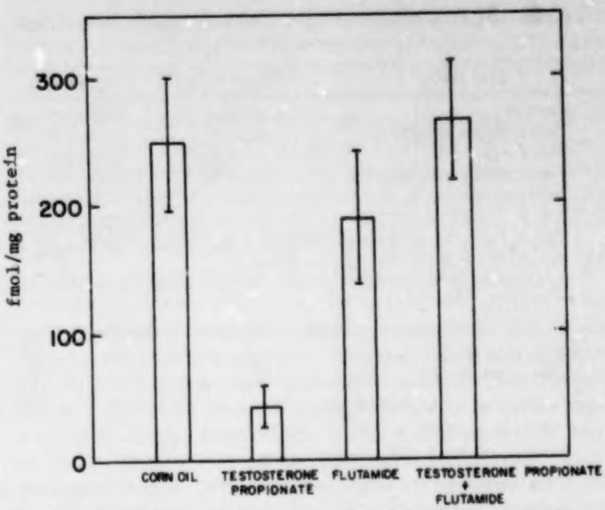
Effect of flutamide on progesterone receptor levels in tumor and uterus from control and testosterone-treated intact rats.—To test

---

[7] In none of the other experiments described in this paper did a change in protein concentration as a result of hormone manipulation affect the results presented.



TEXT-FIGURE 4.—Effect of varying doses of dihydrotestosterone (DHT) benzoate and testosterone (TEST.) propionate on progesterone receptor levels in the MT-W9B tumor grown in WF female rats. Rats were given sc injections five times/wk, starting 32 days after transplant, with DHT benzoate (0.05, 0.5, or 5 mg/kg body wt), TEST. propionate (0.05, 0.5, or 5 mg/kg), or the corn oil vehicle. Rats were killed 24 hr after the last injection, 49 days after transplant (13 total injections). Statistical significance: control vs. DHT (0.05), not significant; control vs. DHT (0.5), not significant; control vs. DHT (5), $P<0.02$; control vs. TEST. propionate (0.05), not significant; control vs. TEST. propionate (0.5), not significant; control vs. TEST. propionate (5), $P<0.02$. For meanings of *bar* and *numbers in parentheses*, *see* legend for test-fig. 1.

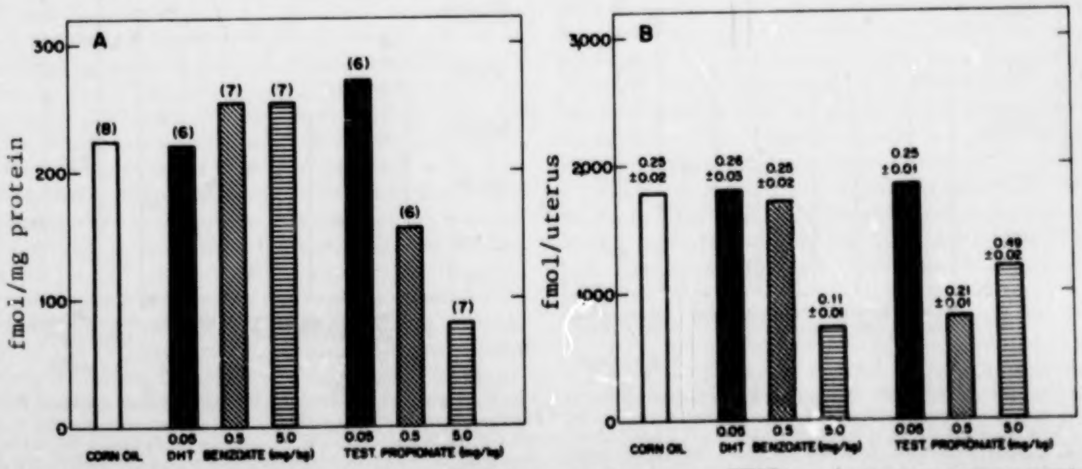


TEXT-FIGURE 5.—Effect of flutamide on the testosterone-induced decrease in cytosol progesterone receptor levels in the MT-W9B tumor grown in WF female rats. Rats were given sc injections five times/wk starting 25 days after transplant, with testosterone propionate (0.5 mg/kg), flutamide (20 mg/kg), the combination of testosterone propionate and flutamide, or the corn oil vehicle. Rats were killed 24 hr after the last injection, 37 days after transplant (eight total injections). *Each bar* represents mean ± SEM of 10 rats/group. Statistical significance: control vs. testosterone propionate, $P<0.01$; testosterone propionate vs. testosterone propionate + flutamide, $P<0.01$; control vs. flutamide, not significant; control vs. testosterone propionate + flutamide, not significant.

whether the androgen effect was mediated through an androgen receptor mechanism, we performed an experiment to determine if the antiandrogen flutamide would block the response. Flutamide, at a dose of 20 mg/kg, completely blocked the inhibitory effect of 0.5 mg testosterone propionate/kg on progesterone receptor levels in the MT-W9B tumor (text-fig. 5). By itself, flutamide had no significant effect. Tumor weight was slightly, although not significantly, increased by testosterone propionate and decreased by flutamide (table 4). Tumors from rats receiving the combined regimen were significantly ($P<0.05$) smaller than those from the control animals.

In uterus from the same animals, neither testosterone nor flutamide had any significant effect on progesterone receptor levels; however, the combination resulted in a significant increase when expressed both as femtomoles per milligram protein and as femtomoles per uterus (text-fig. 7). None of these treatments had any effect on the weight of the uterus (table 4).

Competition of dihydrotestosterone and testosterone for binding of [^{3}H]progesterone to tumor and uterus.—Both testosterone and dihydrotestosterone competed for [^{3}H]progesterone binding to tumor; however, the affinity was much less than that of progesterone (text-fig. 8). Similar observations were made in the uterus (data not shown). Physiologically, this would result in interference of the action of progesterone only if



TEXT-FIGURE 6.—Effect of varying doses of dihydrotestosterone (DHT) benzoate and testosterone (TEST.) propionate on progesterone receptor levels in uterus. Uteri are from the same animals described in the legend to text-fig. 4. Assays were done on pooled uteri (3–10 uteri/group, depending on size of uterus). A) *Numbers in parentheses* represent No. of rats/group. B) *Numbers above bars* represent mean wt (g) of the uterus ± SEM.

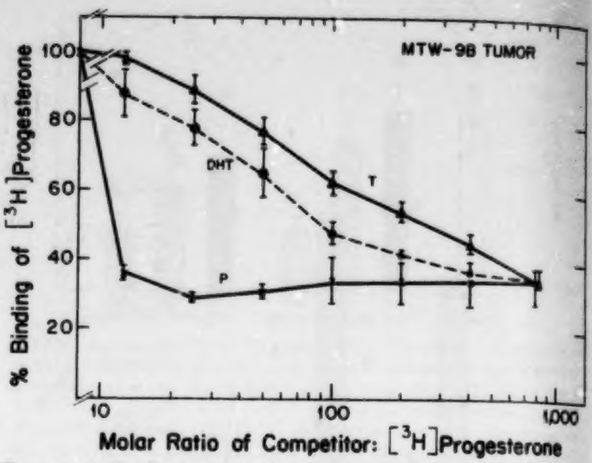
TABLE 4.—*Effect of testosterone propionate and flutamide on tumor and uterus weight*[a]

Rat group	Tumor wt, g	Uterus wt, g
Control	3.52±0.63	0.36±0.02
Testosterone propionate	4.65±0.81	0.35±0.02
Flutamide	2.73±0.45	0.35±0.02
Testosterone propionate + flutamide	2.50±0.39[b]	0.35±0.01

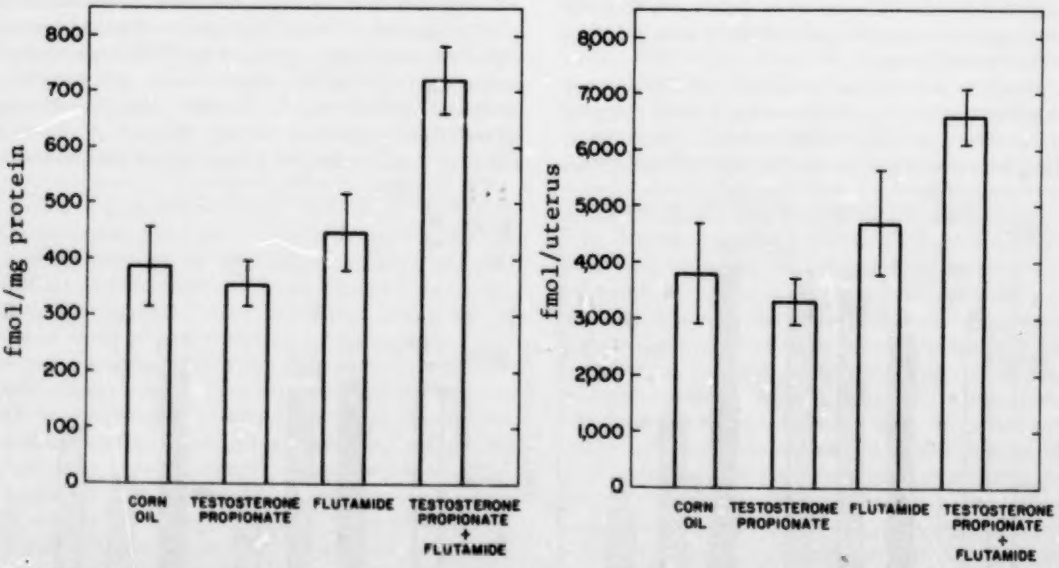
[a] This is the same experiment described in the legend to text-fig. 5. Values are means ± SEM of 10 rats/group.

[b] Significantly different than testosterone propionate alone ($P<0.05$).

the level of androgen relative to progesterone was high. One could argue that our observed effect of testosterone on progesterone receptor levels was due to the fact that the testosterone was not sufficiently cleared by the rats at the time they were killed (24 hr after injection) and that, as a result, testosterone interfered in the progesterone receptor assay by virtue of its binding to the progesterone receptor. We do not think this is so, however, on the basis of two additional experiments. In the first of these, we found that tumor cytosol progesterone receptor levels returned to normal 16 hours after a single injection of 5 mg testosterone/kg. Whereas the decrease observed at earlier time periods could have been due to testosterone occupation of progesterone receptor sites, this testosterone occupation did not result in nuclear translocation of this receptor (data not shown). In the second experiment, we found that the effect of testosterone on progesterone receptor levels in the tumor was not manifested until after 4 days of therapy (5 mg testosterone/kg, daily, with the rats being killed 24 hr after the final injection). If testosterone was simply interfering in the progesterone receptor assay, the effect would have been observed after only a single injection (data not shown). Possibly, endogenous androgen partially interfered in the progesterone receptor assay in tumors from male rats; a portion of the increase in progesterone receptor levels after castration could be due to clearance of this endogenous androgen.



TEXT-FIGURE 8.—Competition of progesterone (P), dihydrotestosterone (DHT), and testosterone (T) for [^{3}H]P binding to MT-W9B mammary tumor cytosol. Cytosol was incubated in the presence of 11 n*M* [^{3}H]P plus varying concentrations of unlabeled steroid as described in "Materials and Methods." *Each bar* represents the mean ± SEM of three separate determinations and is plotted as specific binding. A thousand-fold-molar excess of hydrocortisone was present in all cases to correct for binding of P to the hydrocortisone-binding globulin.



TEXT-FIGURE 7.—Effect of flutamide and testosterone on progesterone receptor levels in uterus. Uteri are from the same animals described in legend to text-fig. 5 and were assayed individually. *Each bar* represents mean ± SEM of 10 rats/group. Statistical significance: progesterone receptor as fmol/mg protein: control vs. testosterone propionate, not significant; control vs. flutamide, not significant; control vs. testosterone propionate + flutamide, $P<0.01$; testosterone propionate vs. testosterone propionate + flutamide, $P<0.01$; flutamide vs. testosterone propionate + flutamide, $P<0.01$. Progesterone receptor as fmol/uterus: control vs. testosterone propionate, not significant; control vs. flutamide, not significant; control vs. testosterone propionate + flutamide, $P<0.02$; testosterone propionate vs. testosterone propionate + flutamide, $P<0.01$; flutamide vs. testosterone propionate + flutamide, not significant.

DISCUSSION

Our results suggest that androgen is a negative modulator of the cytosol progesterone receptor in the MT-W9B mammary tumor. However, the inhibitory effects of androgen on progesterone receptor levels in the MT-W9B tumor and in the uterus as found in this study appear to differ from several reports: Zava and McGuire (*7*), for example, showed that high concentrations (10^{-6} *M*) of dihydrotestosterone resulted in a threefold increase in progesterone receptor levels in the human breast cancer cell line MCF-7, whereas 10^{-8} *M* had no effect. This result appeared to be due to translocation of the estrogen receptor by high, but not low, concentrations of dihydrotestosterone (*7*) and was accompanied by an increased incorporation of leucine and thymidine into protein and DNA, respectively, (*6, 32*) and by a stimulation of cell growth (*7*). Garcia and Rochefort (*13*) also noted that a very high dose of dihydrotestosterone (50 mg/rat) increased progesterone receptor levels and [^{3}H]leucine incorporation in DMBA-induced mammary tumors and concluded also that this was the result of translocation of the estrogen receptor. Testosterone and dihydrotestosterone have also been shown to cause movement of the estrogen receptor into uterine nuclei. This was demonstrated both in vitro at concentrations greater than 10^{-7} *M* (*15, 16, 18, 21, 33*) and in vivo when the androgen in an oil vehicle was injected at a dose greater than 3 mg per rat (*17, 20*). Accompanying this increase in nuclear estrogen receptor was an increased synthesis of induced protein (*18, 20, 21*) and an increased level of progesterone receptor (*19*). Lower doses in vivo (0.3 mg/rat) of dihydrotestosterone in oil (*19*) had no effect, either stimulatory or inhibitory, on progesterone receptor levels.

In our experiments we did not see an increase in progesterone receptor levels (expressed as fmol/mg protein) in uterus after the administration of high doses of 5 mg dihydrotestosterone/kg and 50 mg testosterone propionate/kg (data not shown). In fact, testosterone propionate at doses greater than 0.5 mg/kg caused a decrease. Our results with dihydrotestosterone are in agreement with those reported by Schmidt and Katzenellenbogen (*19*), if it is assumed that the doses we used, 5 mg/kg and lower, were too small to exert an effect on estrogen receptor translocation. That this might be the case is also suggested by the work of Garcia and Rochefort (*20*) and of Schmidt et al. (*18*). To our knowledge, no one has reported any effect of testosterone on progesterone receptor levels in uterus, although in in vitro experiments testosterone was shown to be less effective than dihydrotestosterone in stimulating synthesis of the induced protein (*18, 21*). Schmidt et al. (*18*) showed that 0.5 mg testosterone (in oil) given to an immature rat (roughly comparable to our 5 mg/kg in a mature rat) did not cause translocation of the estrogen receptor and did not increase synthesis of the induced protein, although uterine weight was slightly increased. Our dose of 5 mg/kg causd a uterotrophic response in both intact and ovariectomized rats and decreased progesterone receptor concentrations (expressed as fmol/mg protein) in both groups of rats.

The lack of stimulation of progesterone receptor levels in the MT-W9B tumor by either dihydrotestosterone or testosterone could be explained on the basis of an insufficient dose to cause translocation of the estrogen receptor, although even 50 mg testosterone propionate/kg given to intact rats was inhibitory. We believe, however, that androgens are important modulators in their own right, independent of any estrogenic effects that might be exerted at high concentrations. The antiestrogenic properties of androgen are well established, and an inhibitory effect of androgen on the estrogen-induced increase in progesterone receptor levels, as reported here, has also been described, for example, in hamster kidney (*34*) and in the MCF-7 cell line (*35, 36*). Such an inhibitory effect may be mediated by a decreased concentration (*4*) or a decreased replenishment (*37, 38*) of the cytosol estrogen receptor or by competition for the nuclear binding site(s). The inhibitory effect of physiologic levels of androgen on progesterone receptor concentrations in tumors from castrated and intact male rats has not, however, been previously described, nor has the inhibitory effect of relatively low concentrations of dihydrotestosterone or testosterone in tumors from female rats. Whereas the androgen effect on progesterone receptor levels could still represent antagonism of physiologic levels of estrogen in both male and female rats, we theorize that the androgen is the controlling factor, an argument further strengthened by the data showing that androgen is acting via an androgen receptor-dependent mechanism. Furthermore, the antiestrogen tamoxifen, at doses that blocked the estrogen-induced progesterone receptor response in ovariectomized rats, has no effect on basal levels of progesterone receptor in this tumor (*39*), again suggesting that in the present experiments androgen is acting through an androgen receptor-dependent mechanism rather than as an antiestrogen.

The apparent inhibitory effect of androgen on progesterone receptor levels could, also, be the result of selection of cells with different biochemical properties—an explanation applicable as well to the uterus, since both 5 mg testosterone/kg and 17β-estradiol stimulated uterine growth in ovariectomized rats, whereas testosterone decreased and estrogen increased progesterone receptor levels. Thus testosterone and 17β-estradiol may be stimulating growth of different subpopulations of uterine cells [as has been demonstrated histologically (*40*)], and either the population stimulated by testosterone might have inherently lower levels of progesterone receptor or testosterone might exert an inhibitory control on progesterone receptor levels. The observation that testosterone was not able to block the estrogen-induced increase in progesterone receptor levels in ovariectomized rats to any significant extent is in agreement with the idea that different subpopulations are being induced, as is the fact that the combination of 17β-estradiol and testosterone indicates synergism in terms of uterine weight.

In the tumor, however, we believe that the results cannot be explained on the basis of differential stimulation of cell types for the following reasons: 1) In ovariectomized rats, androgen completely blocked the estrogen-induced increase in progesterone receptor levels. If it is assumed that estrogen and androgen each stimulate different cell types (as in uterus, for example), then different cell types should be present when both hormones are given, and we might expect to see what appears to be only a partial block, as was observed in the uteri from the same animals. A complete block as found in the tumor suggests that androgen is not acting as a selective inducer to a specific cell type but rather (in the presence of estrogen) as an antiestrogen. 2) Flutamide is an antiandrogen that is thought to act by an inhibition of androgen uptake and/or by inhibition of nuclear binding of androgens in the target tissues (*41*). If androgen were to select for growth of a specific cell type, then flutamide would be an unlikely blocker. Rather, the ability of flutamide to prevent the androgen-induced decrease in tumor progesterone receptor levels suggests that the androgen effect is a direct one.

The physiologic significance of the decrease in progesterone receptor levels in the MT-W9B mammary tumor as a result of androgen treatment remains to be established. However, Walters and Clark (*42*) demonstrated that the progesterone-induced decrease in progesterone receptor levels in uterus does result in a decreased ability to respond to progesterone. With the widespread use of progestogens, such as medroxyprogesterone acetate in the treatment of breast cancer (*43*), androgen modulation of progesterone receptor levels has clinical relevance; studies in this laboratory are continuing in an effort to more clearly understand the mechanisms involved.

In Vitro Measurement of Resistance to Phalloidin and γ-Glutamyltransferase of Carcinogen-Induced Preneoplastic Hepatocytes of Rats[1,2]

Norimasa Sawada,[3] Kazunori Furukawa,[3] *and* **Hideyuki Tsukada[3,4]**

ABSTRACT—Male inbred F344 rats weighing about 150 g were fed continuously a diet containing 0.02% *N*-2-fluorenylacetamide for 14–15 weeks. The presumptively preneoplastic hepatocytes were transferred to an in vitro system after dispersion by a collagenase-perfusion technique. Sensitivity to phalloidin in terms of formation of cytoplasmic blebs on the cell surface was less in the presumptively preneoplastic hepatocytes than in normal hepatocytes. Among the presumptively preneoplastic hepatocytes, the γ-glutamyltransferase (GGT)-positive cells were less sensitive to phalloidin than GGT-negative cells, indicating a greater contribution to the decrease in the sensitivity to phalloidin of the presumptively preneoplastic cells.—JNCI 1982; 69:683–686.

It has been well documented that acquisition of resistance of hepatocytes to acute cytotoxicity of hepatocarcinogens or hepatotoxins is a unique biologic property of the cells emerging during hepatocarcinogenesis (*1–8*).

Phalloidin is a specific hepatotoxin (*9*) that induces the formation of cytoplasmic blebs over the cell membranes in an in vitro experiment (*10*). Furthermore, the formation of the blebs was reported to decrease as the treatment of rats with a carcinogen was prolonged, resulting presumably from a decrease in the cellular uptake of the toxin (*6*). However, GGT is one of the most widely used markers for presumptive preneoplasia (*11–16*). Furthermore, it was possible that GGT-positive hepatocytes would acquire relative resistance to cytotoxic effects of 2-FAA (*17*).

In the present experiments, sensitivity to phalloidin of presumptively preneoplastic hepatocytes of rats induced by 2-FAA was quantitatively assessed in the in vitro system, and correlation between the sensitivity and GGT-positiveness of the cells was investigated cytochemically.

MATERIALS AND METHODS

Animals.—Male F344 rats weighing about 150 g were fed a commercial diet (NMF; Oriental Yeast Co., Tokyo, Japan) containing 0.02% 2-FAA for 14–15 weeks ad libitum. Prior to examinations, the animals were placed on the diet without 2-FAA for 5 days. Animals were maintained at 22±1°C and subjected to a standard 12-hour light–dark schedule (6 a.m.–6 p.m.).

Isolation of hepatocytes.—Hepatocytes were isolated by a collagenase perfusion technique as described previously in detail (*7, 18*). In the present experiments, the perfusion time of Ca^{2+}-free Hanks' balanced salt solution containing 130 U collagenase/ml (Sigma Chemical Co., St. Louis, Mo.) was 10 minutes, and the flow rate of the perfusion was 57 ml/minute. Presumptively preneoplastic hepatocytes were obtained from whole livers of rats administered 2-FAA. After viability of the cells was examined by the trypan blue exclusion test (viabilities in this experiments were 85–90%), the cell suspension was prepared at a concentration of 6×10^5 viable cells/ml in Williams' medium E (Flow Laboratories, Inc., Rockville, Md.) supplemented with 10% calf serum (GIBCO, Grand Island, N.Y.), 0.5 μg insulin/ml, 0.04 mg streptomycin/ml, and 40 IU penicillin-G/ml.

Treatment with phalloidin and GGT cytochemistry.—To 1 ml of the cell suspension containing 6×10^5 viable cells was added 1 ml of the medium containing various concentrations of phalloidin (Sigma Chemical Co.) but devoid of serum, and they were incubated for 20 minutes at 37°C with slow shaking (*19*). After incubation, the mixtures were immediately cooled to stop the phalloidin action (*20*). After added trypan blue solution, the cells that were viable and that had formed cytoplasmic blebs were counted in each examination. The phalloidin response was expressed as a percentage of the number of the cells that had formed the multiple blebs over the cell surface to the total number of the observed viable cells. Phalloidin-induced bleb formation was observed only in viable cells but not in nonviable cells as reported by Frimmer et al. (*21*). In GGT cytochemical examination, 1.5 ml of the cell suspension was inoculated into 35-mm plastic dishes in which cover glasses were placed. After 3-hour cultivation in a CO_2-incubator, the cells were washed three times with the culture medium and then incubated with 1.5 ml of the phalloidin-containing medium for 20 minutes at 37°C. After the incubation, more than 95% of the cells attached to the cover glasses were viable, even in the presence of 10 μg phalloidin/ml, when examined by trypan blue exclusion test. The cells on the cover glasses were fixed in ice-cold acetone for 15 minutes and stained for GGT activity according to the method of Rutenberg et al. (*22*).

RESULTS

As for the purity of the cell suspensions, obtained from both normal and the carcinogen-induced preneoplastic livers, more than 98% of the cells were identified as hepatocytes

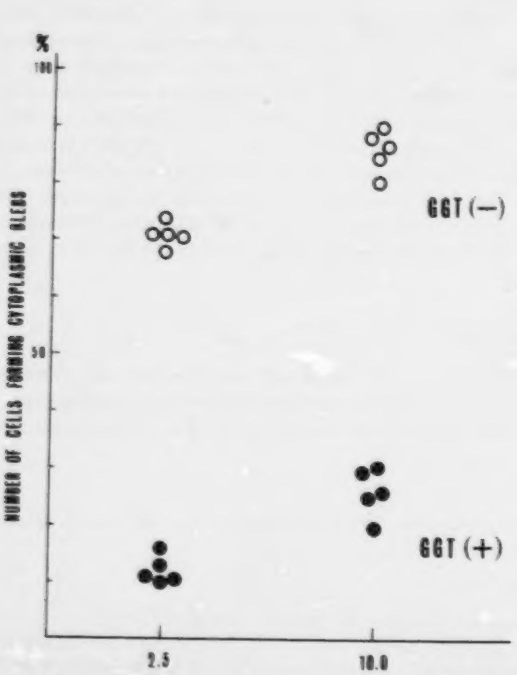
TEXT-FIGURE 1.—Sensitivity to phalloidin of normal and preneoplastic hepatocytes. ○=normal hepatocytes (n=6). ●=preneoplastic hepatocytes (n=6). Values are means ± SD.



TEXT-FIGURE 2.—Sensitivity to phalloidin of GGT-positive and GGT-negative carcinogen-altered hepatocytes. ○=GGT-negative cells. ●=GGT-positive cells.

by the aid of alkaline 3,3′-diaminobenzidine staining fo peroxisomes.

As shown in figures 1 and 2, we quantitatively assesse sensitivity to phalloidin of hepatocytes by counting th proportion of the cells that had formed multiple cytoplasmi blebs. Text-figure 1 shows that at every concentration of th toxin examined the cells obtained from the carcinogen treated rats were more resistant to phalloidin than norma hepatocytes. The difference in the degree of the sensitivit between those two cell populations was more conspicuous a the concentration of phalloidin was lower.

The presumptively preneoplastic hepatocytes were divided into 2 groups according to GGT cytochemistry. On group was GGT-positive and the other was GGT-negativ (figs. 3, 4). Of the presumptively preneoplastic hepatocytes 30–40% were GGT-positive cells. The sensitivity of thes groups of cells was examined. As shown in text-figure 2, a concentrations of 2.5 and 10 µg phalloidin/ml, the sensitivity of GGT-positive cells was about 10 and 25%, respectively In contrast, the sensitivity of GGT-negative cells was abou 70 and 85%, respectively. GGT-positive cells were mor resistant to phalloidin than were GGT-negative cells, th former cell group making a greater contribution to th increase in the resistance of presumptively preneoplasti hepatocytes than the latter.

DISCUSSION

Resistance of presumptively preneoplastic hepatocytes to hepatocarcinogens or hepatotoxins is considered as one o characteristic features that the cells were rendered to surviv and proliferate selectively during the carcinogenesis. In thi context, resistance of presumptively preneoplastic rat hepatocytes to aflatoxin (*5*, *6*), methotrexate (*8*), cycloheximid (*8*), adriamycin (*8*), and dimethylnitrosamine (*7*) was reported on in vitro experiments, which were favorable for a quantitative assessment of the degree of the resistance. Furthermore, our previous experiments (*7*, *18*) on dimethylnitrosamine cytotoxicity showed that resistance of preneoplastic rat hepatocytes induced by 2-FAA was increased as th preneoplastic stages progressed.

Phalloidin is a polypeptide that acts specifically on hepatocytes resulting in vitro in the formation of cytoplasmic blebs. In contrast to the above-mentioned cytotoxic agents phalloidin was reported to act on the cell membranes inducing the cell death in an environment containing an excess of Ca^{2+} ions (*23*). However, the cytoplasmic bleb formation test might be much more sensitive than the trypan blue exclusion test in assessing the sensitivity of the cells to phalloidin, since much smaller amounts of the toxin and a shorter period of the treatment were observed to be enough for the cytoplasmic bleb formation test.

During hepatocarcinogenesis, sensitivity of the cells to phalloidin was reported to be decreased progressively as the carcinogen-treatment period was prolonged, presumably due to an impairment in the transport system of the toxin across the cell membranes or to an alteration of the receptor for the toxin on the cell surface (*6*). These findings that the phalloidin response was decreased in carcinogen-altered hepatocytes might agree with those of the present results.

Expression of GGT activity of hepatocytes in carcinogenesis is considered to be a fetal phenotypic expression and may be due to an alteration of cell membrane (*24*). In the present study it was demonstrated that the increase in GGT activity was well correlated with the decrease in sensitivity to phalloidin. It is suggested that alterations of the cell membranes occur in a preneoplastic state in terms of expression of GGT activity, on the one hand, and decrease in phalloidin response, on the other hand.

Chicken Resistance to Dimethylnitrosamine Acute Effects on the Liver: A Comparative Study With Other Species[1,2,3]

H. M. Godoy,[4] M. I. Díaz Gómez,[4] A. Marzi,[4] E. C. de Ferreyra,[4] O. M. de Fenos,[4] *and* J. A. Castro[4,5]

ABSTRACT—Dimethylnitrosamine (DMN)-induced liver damage, as measured by the increase in plasma isocitrate dehydrogenase as well as by histologic assessment of necrosis, was marked after DMN ip administration (70 mg/kg) in males of all noninbred species tested (BALB/c mouse, Sprague-Dawley rat, Syrian golden hamster, general purpose guinea pig) but not in the noninbred White Leghorn chicken. At 1 and 3 hours after DMN injection, liver DMN levels were not lower in the chicken as compared to levels in the other species. Furthermore, in all species except the chicken, significant decreases were found at 3 hours as compared to 1 hour after DMN administration. DMN metabolism to CO_2 and to formaldehyde, as well as covalent binding of DMN-reactive metabolites to either proteins or nucleic acid, was measured with the use of liver slices, microsomes, and/or 9,000×*g* supernatants. Results indicated that chicken liver had a very low capacity for metabolism and activation (29–3,166 times lower than comparable data in mice or hamsters).—JNCI 1982; 69:687–691.

Nitrosamines have been implicated as acute liver toxicants, mutagens, carcinogens, and teratogens (*1–3*). Biologic effects of nitrosamines are thought to be mediated through the formation of reactive metabolites that react with cellular macromolecules (*1, 2*). Numerous animal species, including mammals, birds, fish, and amphibia, are susceptible to the carcinogenic action of an N-nitrosamine (*1–4*). Relatively less information is available about species susceptibility to nitrosamines' acute effects on the liver (*1–4*). The chicken is remarkably resistant to acute liver effects produced by a hepatotoxin, such as carbon tetrachloride, that causes injury by metabolic activation (*5–8*). In this work, we studied whether chicken liver is also resistant to DMN acute toxic effects. In addition, we compared the susceptibility to DMN acute effects on the liver of the chicken with that of other species, such as the mouse, rat, hamster, and guinea pig. We also attempted to correlate the observed effects with the intensity of different parameters related to DMN metabolism and/or activation to reactive metabolites.

MATERIALS AND METHODS

Chemicals.—Gold label quality DMN was purchased from the Aldrich Chemical Co., Milwaukee, Wis., and [^{14}C]DMN (50.1 mCi/mmol, purity >99% by GLC) from New England Nuclear Corp., Boston, Mass. All other chemicals were of the best quality available.

Animals and treatment.—All the experiments were performed with animals of the following noninbred species fasted for 12–14 hours: male Sprague-Dawley rats, 250–350 g each; male BALB/c mice, 20–25 g; male general purpose guinea pigs, 280–300 g (purchased from Centro Panamericano de Zoonosis, Buenos Aires, Argentina); male Syrian golden hamsters (purchased from the Centro Panamericano de Zoonosis), 90–100 g; White Leghorn chickens (from Romanelli Laboratories, Buenos Aires), 1,500–1,900 g.

DMN was given ip in 0.9% NaCl solution at a dose of 70 mg/kg. Controls received 0.9% NaCl solution. In the toxicity studies, animals were killed 24 hours after DMN administration. Blood samples were taken with a heparinized syringe under light ether anesthesia from the inferior venae cava.

Tissue preparations for determination and measurements.—Liver slices were prepared with a Stadie Riggs hand microtome. The slices (≈200 mg) were equilibrated with O_2 in Warburg flasks containing 2.8 ml Krebs-Ringer buffer-glucose (2 mg/ml) (*9*). [^{14}C]DMN was added from the side arm, and $^{14}CO_2$ was trapped in NaOH (0.2 ml, 10% wt/vol). The NaOH was then removed from the well, the [^{14}C]carbonate was precipitated as barium carbonate, and the radioactivity was determined (*10*). Binding of ^{14}C from [^{14}C]DMN to nucleic acids in tissue slices was performed by isolation of nucleic acids according to the procedure described by Korn (*11*) followed by hydrolysis with 5% TCA at 90°C for 15 minutes. Radioactivity on an aliquot was counted with the use of a cocktail composed of 0.6% PPO in Triton X-100–toluene (1:4, vol/vol). The in vitro metabolism to formaldehyde and the activation of DMN to reactive metabolites by 9,000×*g* supernatants or microsomes were determined as described by McLean and Day (*12*), but [^{14}C]DMN (0.17 m*M*, 1.8×10^6 dpm/ml) was used instead of DMN. Samples were incubated in a Dubnoff shaker for 10 minutes at 37°C, and the reaction was stopped with an equal volume of 10% TCA. The irreversibly bound radioactivity was determined in the acid-insoluble precipitate as described (*13*). [^{14}C]formaldehyde produced from [^{14}C]DMN was measured in the TCA-soluble fraction as previously described (*14*).

NADPH-linked ICDH activity was measured according to the method of Sterkel et al. (*15*). One unit of activity was the amount of enzyme producing 1 mmol NADPH/ml plasma/hour at 25°C.

DMN levels in liver were determined as follows: Liver homogenates (30% wt/vol in water) were deproteinized with a mixture (20% wt/vol of zinc sulfate and saturated barium

hydroxide). After centrifugation, aliquots of supernatants were saturated with sodium chloride and extracted with an equal volume of methylene chloride. The methylene chloride extracts were dried with anhydrous sodium sulfate, and DMN concentrations were determined by GLC coupled to a thermal energy analyzer (Thermal Electron Corp., Waltham, Mass.). Separation was performed in 20 *M* Carbowax/0.5% KOH on Chromosorb W/HP 80–100 mesh. Column temperature was 175°C. The recovery of known amounts of DMN spiked in liver homogenates was 70–75%. Reported values were corrected for loss.

Histologic techniques.—After the liver was removed, small portions from the left and central lobes were immediately fixed in Bouin's solution, embedded in paraffin, and stained with hematoxylin and eosin. The specimens were coded to avoid bias and were evaluated histologically by at least two independent observers. To quantify the morphologic changes, we graded liver sections according to hydropic degeneration or necrosis by means of an arbitrary scale (+=light; ++=moderate; +++=marked; ++++=very intense).

Statistical method.—Results reported as representative for each experimental condition were the means of all the observations made. Five livers per group and five sections per liver were inspected. The significance of the difference between two mean values was assessed by Student's *t*-test (*16*).

RESULTS

DMN metabolism to CO_2 and CB of DMN metabolites to nucleic acids in experiments with liver slices from different animal species.—All the species tested were able to metabolize DMN to CO_2 and to give DMN-reactive metabolites, which to some extent bound covalently to nucleic acids (table 1). However, there are very large differences among the species in their ability to carry forward both processes. Metabolism of DMN was 25 times more intense in hamsters than in chickens. The intensity of the CB of ^{14}C from [^{14}C]DMN to the nucleic acids in liver slices from different animal species followed a similar pattern, but differences between the species were not so large as they were for metabolism of DMN to CO_2 (table 1).

Hamster	22.9±1.61	2.02±0.46
Rat	4.7±0.95	1.53±0.6
Chicken	0.79±0.18	0.16±0.03

[a] Liver slices were equilibrated with O_2 in a Warburg flask containing Krebs-Ringer buffer-glucose. [^{14}C]DMN (0.1 m*M* final concentration, 1×10^6 dpm/ml) was added from the side arm, and $^{14}CO_2$ was taken up with NaOH at the center well, precipitated as barium carbonate, and counted, as detailed in "Materials and Methods." Liver slices were taken from 3 rats.

[b] Reported $^{14}CO_2$ production or CB values correspond to incubation periods of 120 min at 37°C.

TABLE 2.—*Formaldehyde formation from DMN and CB of ^{14}C from [^{14}C]DMN to proteins by microsomes or 9,000×g supernatants from liver of different animal species[a]*

Species	Microsomes	9,000×*g* supernatants
Formaldehyde formed, 10^{-6} μmol/g liver/10 min[b]		
Mouse	180,400±15,500	37,950±9,900
Guinea pig	55,560±17,510	45,500±11,500
Hamster	150,300±23,500	127,740±32,100
Rat	5,700±2,300	16,500±5,000
Chicken	492±339	197±338[d]
CB, μmol/g liver, $\times10^{-6}$[c]		
Mouse	3,886±935	3,235±863
Guinea pig	9,440±2,295	4,072±886
Hamster	29,760±4,200	12,950±3,590
Rat	183±60	1,164±650
Chicken	9.4±19.0[d]	18.4±29.0[d]

[a] Livers were blended with 0.15 *M* KCl in a Potter-Elvehjem homogenizer and centrifuged 20 min at 9,000×*g*. The supernatant was then centrifuged 60 min at 105,000×*g* to obtain microsome fraction.

[b] The final protein concentration in the incubation mixture was 2.5–3.8 mg/ml for microsomes and 8–10 mg/ml for 9,000×*g* supernatants. The incubation mixture contained [^{14}C]DMN (0.17 m*M*, 1.6×10^6 dpm/ml) and an NADPH-generating system. Samples were incubated for 1 min at 37°C. Results are the means of three determinations. Fo formaldehyde determinations in the incubation mixture, a known amount of carrier formaldehyde was added and precipitated with 5,5-dimethyl-1,3-cyclohexanedione. A weighed portion of formaldemethone formed was counted in a toluene–PPO mixture. *See* "Materials and Methods" for other details. Values are means ±SD.

[c] For CB studies, proteins were precipitated with TCA, delipidated and dried with successive washings with the use of a mixture of ethanol plus ether plus chloroform (2:2:1), acetone, and ether; finally, they were dissolved in concentrated formic acid and counted with a Butyl Cellosolve–PPO mixture. *See* "Materials and Methods" for details. Values are means ± SD.

[d] Not significantly different from zero.

Formaldehyde formation from DMN by microsomes or 9,000×g supernatants from livers of different animal species.—Both microsomes and 9,000×*g* supernatants from the mouse, guinea pig, hamster, or rat were able to metabolize DMN to formaldehyde. The chicken, in contrast, exhibited DMN demethylase values either not significantly different from zero or extremely low (table 2). The ratio between DMN demethylase activity in microsomes to that in 9,000×*g* supernatant varies from one species to another. For example, for the mouse and chicken a higher activity was found in microsomes than that in 9,000×*g* supernatants, whereas the ratios were similar in the guinea pig or hamster; in the rat 9,000×*g* supernatants exhibited higher activity than did the microsomes (table 2).

*CB of ^{14}C from [^{14}C]DMN to protein in microsomes and 9,000×*g *supernatants from livers of different animal species.*—Both microsomes and 9,000×*g* supernatants from the livers of the different animal species except the chicken were able to activate DMN to reactive metabolites that bind covalently to proteins (table 2). For the chicken, values were not significantly different from zero. The extent of the CB in the hamster was higher than that in the other species in both microsomes and 9,000×*g* supernatants and was more than three times as intense as that in the guinea pig. CB in the guinea pig was of the same order of magnitude of that in the mouse, which in turn was far more intense than that

TABLE 3.—*DMN levels in livers from animals of different species 1 or 3 hours after administration*[a]

Species	DMN content, µg/g liver, at hr:	
	1	3
Mouse	26.9±6.4	4.6±2.6
Guinea pig	71.7±8.9	48.8±6.4
Hamster	43.2±22.6	13.5±2.0
Rat	58.1±5.8	50.1±8.2
Chicken	67.1±20.3	84.8±12.6

[a] Animals received an ip injection of 70 mg DMN/kg and were killed at 1 or 3 hr after injection. Their livers were homogenized, extracted with methylene choride, and analyzed by GLC coupled to a thermal energy analyzer. Each group had 8 animals. Values are means ± SD.

in the rat. In the hamster and guinea pig the intensity of the CB was higher with microsomal than with 9,000×*g* supernatant preparations. In the mouse, the intensity of the CB was similar in both fractions, whereas in the rat it was far more intense in 9,000×*g* supernatant preparations than in microsomes (table 2).

DMN levels in livers from different animal species 1 to 3 hours after administration.—Administration ip of 70 mg DMN/kg body weight to animals of different species led at 1 hour to liver DMN levels of the same order but of different magnitude (table 3). The differences were larger at 3 hours. Decreases in the liver DMN content at this time were more pronounced in the mouse than in the hamster, and these decreases in the hamster were larger than that observed either in the guinea pig or in the rat. DMN levels in the liver from a chicken at 3 hours did not decrease but rather increased slightly (table 3).

DMN-induced damage in livers of animals of different species.—Twenty-four hours after ip administration of a single dose of 70 mg DMN/kg, centrilobular necrosis of the liver was observed in all species except the chicken, as evidenced by determinations of ICDH in plasma (table 4). Hepatic necrosis also was assessed by histologic examination. The administration of DMN to mice produced a very intense (++++) centrolobular necrosis at 24 hours, associated with hemorrhage and edema. The liver cells of the periportal zones were enlarged, and in that area the normal architectural pattern was lost. Administration of DMN to guinea pigs and hamsters produced centrolobular necrosis at 24 hours (++ and +, respectively). The cells of the periportal zones also exhibited different degrees of necrosis. Administration of DMN to rats produced a centrolobular necrosis (++), little hemorrhage and edema were seen, and the liver cells of the periportal zones were well preserved. At this dose no necrosis was observed in chicken livers.

TABLE 4.—*Effect of DMN 24 hours after administration on ICDH in different animal species*[a]

Species	Treatment	ICDH, U±SD[b]	Degree of histologically observable necrosis[c]
Mouse	Control	160±100	—
	DMN	26,700±10,810[d]	++++
Guinea pig	Control	4,200±1,250	—
	DMN	91,000±3,300[d]	++
Hamster	Control	1,200±1,020	—
	DMN	10,710±6,840[e]	+
Rat	Control	200±60	—
	DMN	7,850±1,450[d]	++
Chicken	Control	675±200	—
	DMN	960±540	—

[a] Controls received 0.9% NaCl solution. Animals were killed 24 hr after DMN administration. Blood samples were taken and plasma was assessed for ICDH activity. Each group had 5 animals.

[b] One unit of enzyme is that required to form 1 nmol NADPH/ml plasma/hr at 25°C.

[c] For meanings of *plus signs, see* "Materials and Methods" (histologic techniques). *Dash* indicates no histologic observable necrosis.

[e] $P<0.01$.

DISCUSSION

Our histologic and enzymatic observations reported here show that chicken liver is resistant to DMN acute necrogenic effects. This behavior resembles the one previously reported for the other hepatotoxin acting on chicken liver, CCl_4 (*5–8*). In the case of CCl_4, this lack of necrogenic effect was attributed to a poor capacity of chicken liver to biotransform CCl_4 to trichloromethyl-free radicals or to the associated lack of production of lipid peroxidation (*7, 8*). Similar reasons might be in operation in the failure of chicken liver to respond to the DMN's acute effects. Chicken liver has far less ability to metabolize and/or activate DMN to reactive metabolites than do the livers of the other species tested. For example, metabolism of DMN to CO_2 in liver is about 29 times less intense in the chicken than in the hamster and 6, 7, and 4 times less than in the rat, mice, or guinea pig, respectively. These results on metabolism of DMN to CO_2 are in agreement with those previously reported by Montesano and Magee (*17*) for hamsters and rats. Again, the ability to activate DMN to reactive metabolites that bind covalently to nucleic acids in the liver is 13 times less intense in the chicken than in the hamster and 10, 8, and 3 times less than that in the rat, mouse, or guinea pig, respectively. Similarly, liver microsomal DMN demethylase in the chicken is 366 times less active than in the mouse and 305, 113, and 12 times less than that in the hamster, guinea pig, or rat, respectively. These results on microsomal DMN demethylase are in agreement with those previously reported by Lotlikar et al. (*18, 19*) for the rat, hamster, and guinea pig. A recent work also reported good correlation between rates of DMN demethylation and relative acute liver toxicities in species such as the monkey, cat, lizard, duck, rat, and guinea pig (*20*).

The covalent binding of DMN-reactive metabolites to liver microsomal proteins, however, is 3,166 times less intense in the chicken than in the hamster and 1,004, 413, and 19 times less than that in the guinea pig, mouse, or rat, respectively. A similar behavior was observed for DMN demethylase activity in liver 9,000×*g* supernatants. In this case, values for the chicken were 648 times less than for the hamster and 231, 193, and 84 times less than the value for the guinea pig, mouse, or rat, respectively. Finally, the CB value of each reactive DMN metabolite to liver 9,000×*g* supernatant protein in chickens is 704 times less than the value in hamsters and 221, 176, and 63 times less than that in guinea pigs or rats, respectively. Moreover, assuming that the time necessary for distribution of DMN through the body is negligible in relation to 3 hours and that the given dose is uniformly distributed among the different tissues, as seems to be the case (*1, 17, 21*), then we may consider that about 70 μg DMN/g liver would be approximately the zero time concentration in livers of the different species receiving ip a dose of 70 mg/kg. The amounts of DMN remaining in the livers after 3 hours revealed that 93.4% of the original amount of DMN was metabolized in mice; 80.7%, in hamster; 30.3%, in guinea pig; and 28.42%, in the rat. In the chicken no decreases were detected in the liver concentrations of DMN; rather a 21.14% increase was observed. This apparent increase probably derives from the comparison based on theoretical assumptions made for this analysis. Results show that the chicken, which is the species less susceptible to deleterious effects by DMN on the liver, is also the one less able to process DMN through different metabolic pathways. The preceding analysis might reasonably explain the large difference in the acute liver response of the chicken to DMN when compared to the responses of other species. However, it is not possible to explain with a similar analysis the different response of the liver to DMN acute effects in species other than the chicken.

An absolute lack of correlation was observed between the necrogenic response of DMN in the liver of the mouse, guinea pig, hamster, and rat and metabolism of DMN to CO_2 or DMN demethylase activity in 9,000×*g* supernatants or the CB of DMN reactive metabolites to proteins either from microsomes or from 9,000×*g* supernatants. Among different species, a partial degree of correlation was observed for necrosis in liver, for DMN demethylase activity in liver microsomes, and for DMN disappearance in 3 hours in livers. In regard to these last two parameters, however, there is an inversion in the correlation for hamsters in relation to that of guinea pigs, inasmuch as the latter are more susceptible to DMN necrogenic effect than the former, whereas the intensity of the above-cited parameters is greater in hamster livers than in guinea pig livers. This lack of correlation between several parameters and DMN-induced liver injury in different species is in contrast with our past findings about correlation between CB to 9,000×*g* supernatant proteins and injury observed in rats (*22–24*). Factors other than DMN metabolism and/or activation might be relevant to inherent susceptibility of livers from different species to DMN necrogenic effects. For example, the cell response to injury as well as its intrinsic ability for repair could be different in the livers of different animal species, thus obscuring correlations with other parameters. Within a given species, e.g., the rat, we (*22–24*) previously reported that DMN acute effects on the liver correlated with extents of CB of DMN metabolites to 9,000×*g* supernatant proteins, but in the present experiments this does not seem to be the case.

Much remains to be learned about the different factors involved in the liver response to injury by DMN and other nitrosamines. That knowledge would be relevant also to long-term carcinogenic effects of these chemicals, inasmuch as cell necrosis is believed to modulate to a great extent the course of the cancer induction by chemicals in organs such as the liver, which are quiescent with respect to cell proliferation (*25*). The mechanism of this effect appears to be an induction of compensatory liver cell proliferation (*26*). Whether chicken liver is susceptible to DMN carcinogenic effects would be of interest. Recent results by Schmähl et al. (*27*) indicated that another nitrosamine, diethylnitrosamine, causes liver cancer in chickens. However, diethylnitrosamine is a more potent carcinogen than is DMN (*1, 2, 4*); nonetheless, no species ever tested against carcinogenic nitrosamines proved to be unsusceptible (*28*).

Effects of Sublethal Irradiation on Changes in Crypts of the Mouse Colon During Treatment With 1,2-Dimethylhydrazine[1,2,3]

Thomas C. Richards[4] *and* **David E. Tacha**[4]

ABSTRACT—The effects of low-dose X-irradiation on the progression of early neoplastic changes induced in the colon by 1,2-dimethylhydrazine (DMH) were assessed. Outbred female Swiss-Webster mice were treated with DMH only, DMH–irradiation, irradiation only, or 0.001 *M* EDTA. Animals were pulsed with [^{3}H]thymidine for 1 hour, and the distal colon was radioautographed. The number of labeled cells per crypt in animals treated with DMH–irradiation was greater (P<0.01) than the number in "DMH-only" animals, but a corresponding increase in the length of the crypts did not occur. After 16 weeks of treatment, the percentage of animals with focal atypia was similar in the DMH–irradiation group (87%), and the DMH-only group (100%), but there were more focal atypias per animal in the DMH-only group. After 20 weeks, 14% of the DMH–irradiation group had visible tumors compared to 63% of the DMH-only group. The results suggest that DMH increased the number of cells at risk for irradiation; thus the surge in proliferation subsequent to cell depletion was amplified. However, the development of precancerous lesions was not promoted.—JNCI 1982; 69:693–697.

Low-dose, whole-body irradiation is cytotoxic to populations of mitotic cells in the proliferative zone of crypts of the mouse colon. The extent of mucosal damage is dependent on the dose level and frequency of irradiation (*1*). The injured or dead cells were sloughed and the colon epithelium is renewed by a compensatory proliferative surge of the remaining stem cells (*2*). The lower regions of crypts in mice begin to show some cell loss 36 hours after high-dose irradiation, and by 60 hours the lower halves of the crypts are depleted. Foci of surviving clonogenic cells become visible in the lower crypt, and within 5 days the number of mitotically active cells will have increased dramatically (*3*).

These alterations in the growth characteristics of crypts may influence the development and progression of lesions induced in the mucosa by the carcinogen DMH. At least two possible events may occur: 1) An increase in proliferative activity may enhance carcinogenesis by the reduction of the latent period for the appearance of focal atypia, or 2) irradiation-induced sloughing of cells, already altered by DMH, may delay carcinogenesis because repopulation of crypts could occur from relatively unaffected stem cells. The purpose of this study was to determine whether the cytokinetics of crypts is different in groups given DMH–irradiation compared to those given DMH alone, and to determine whether the induction of neoplastic lesions by DMH is similar in the 2 groups.

MATERIALS AND METHODS

Animals and treatments.—Outbred, female Swiss-Webster mice, at least 60 days old and 20 g in body weight, were housed 5 animals per cage and given free access to food and water (standard rodent chow; Oregon State University, Corvallis, Oreg.). Nine groups of animals were treated for 1–20 weeks. Each group was divided into 4 subgroups (5 animals/subgroup) and treated with DMH alone, or DMH–irradiation, or irradiation alone, or 0.001 *M* EDTA. More animals were added to those groups that were treated for 16 and 20 weeks. DMH (American Scientific, Portland, Oreg.) was dissolved in 0.001 *M* EDTA and adjusted to pH 6.5 with $NaHCO_3$. Controls were given comparable volumes of 0.001 *M* EDTA. Those subgroups that received DMH or EDTA were given sc injections at a dose of 20 mg/kg body weight on Mondays each week. Subgroups that received irradiation were given 390 rad of whole-body irradiation on Fridays before the beginning of weeks 1, 3, and 6 of the experiment. The mice were irradiated before these weeks of the experiment so that irradiation effects on initial DMH-induced changes in the cells could be tested. All the animals of a group were killed on Thursdays, 3 days after the beginning of weeks 1, 2, 3, 4, 6, 8, 12, 16, or 20 of the experiment.

Irradiation was performed in a cesium-37 irradiator (Mark I, model 68; J.L. Shepherd and Assoc., Glendale, Calif.). Animals in groups of 5 were placed in a transparent plastic box with ample ventilation, rotated slowly on a turntable in the irradiation chamber, and exposed to 223 rad per minute for 1.75 minutes for a total dose of 390 rad. The lethal dose of radiation for mice is about 1,000 rad, so the 390-rad dose was low enough to initiate a proliferative response in the crypt cells without killing the animals (*4, 5*).

Tissue preparation.—Mice were given injections of 0.5 μCi [^{3}H]dThd/g body weight (20 Ci/mmol; New England Nuclear Corp., Boston, Mass.) 1 hour before they were killed. The entire descending colon of the mouse was quickly removed. A section of the distal colon at the pelvic rim 1.0–1.5 cm above the anus was dissected, washed in cold 0.9% NaCl, divided into two sections, each 3–5 mm in length, and fixed in 4% paraformaldehyde–1% glutaraldehyde solution for at least 24 hours. The two sections from each animal were embedded together in one block of glycol methacrylate and oriented so that transverse sections of the colon could be taken. The remainder of the colon was slit lengthwise, washed free of its contents, stained with 1% Alcian blue, and examined under a 2× dissecting micro-

scope. The number of grossly visible tumors was counted in this tissue.

Analysis of tissues.—Two types of microscopic analyses were completed on sections of each colon: 1) radioautographic analysis for identification of cells that incorporate [^{3}H]dThd, and 2) histologic analysis for the presence of focal atypia and other induced lesions. Several sections (2-3-µm thick) were cut on a Sorvall JB-4 microtome and mounted on slides, then 300–500 µm were trimmed from the block, and additional sections were cut. The slides of colon used for radioautography were hydrolyzed in 1 *N* HCl for 10 minutes, stained by the Feulgen method, and dried. These slides were then processed for radioautography with the use of standard procedures (*6*).

The rest of the slides were stained with hematoxylin, counterstained with methylene blue, and the number of abnormal crypts, focal atypias, microcarcinomas, and cysts per section were counted. Focal atypias were characterized by high mitotic activity, disrupted crypt architecture, and anaplastic or abnormal cell structure and size (*7*). When these changes were confined to a single crypt, it was defined as an abnormal crypt (*8*). Microcarcinomas were defined as tumors that were too small to be identified with a dissecting microscope. The presence of mucosal cysts, indicative of disrupted cell kinetics in the glands, were also noted. The intent of this study was to compare relative differences in the number of lesions observed between groups rather than an analysis of the total number of lesions induced per animal.

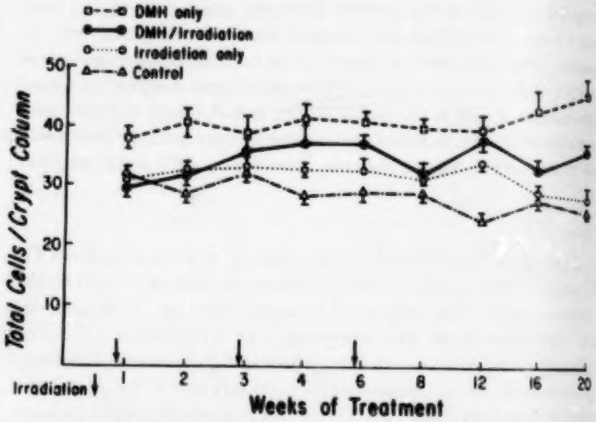
Thirty crypt columns per animal were scanned for the presence of [^{3}H]dThd-labeled cells. The number of labeled cells and their positions in the crypt column were recorded. Differences in cell proliferation among the 4 subgroups of animals after 2, 4, 8, and 16 weeks of treatment were chosen as representative times during the course of the experiment to analyze changes in the distribution of labeled cells. Further details concerning procedures used to analyze the radioautographs can be found elsewhere (*9*).

A one-way analysis of variance was used to test the differences in values among subgroups at any particular point during treatment. Differences in distribution of labeled cells after each time interval among the treatment groups were determined by a two-way analysis of variance (*10*).

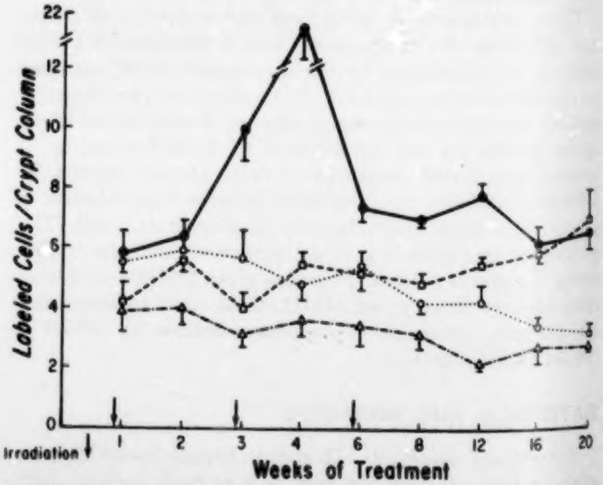
RESULTS

Three consecutive whole-body irradiations, spaced 2 to 3 weeks apart, at sublethal doses of 390 rad per animal resulted in an increase in pyknotic nuclei along the lower halves of crypts as the target cells were killed by irradiation. Instead of the entire mucosa sloughing as occurs with larger doses of radiation, the damaged individual cells were extruded into the crypt lumen and lost from the epithelium.

Radioautographs of colon sections from animals treated with DMH, DMH-irradiation, irradiation only, or untreated were analyzed for the total number of cells and the number of labeled cells per crypt column. In the DMH-treated group we observed an initial, rapid increase in the number of labeled cells and in the total number of cells in the crypts followed by a more gradual enlargement of crypts as the mucosa became severely altered. In contrast, the number of labeled cells per crypt column increased significantly ($P<0.01$) after the 3d week of treatment in the DMH-irradiation group compared to the numbers in the other groups (text-figs. 1, 2). There was no additional acute response to irradiation during the 6th week of DMH treatment, although the expanded level of cell proliferation was sustained until the 12th treatment week in the DMH-irradiation group. A corresponding increase in the total number of cells per column did not accompany the increase in labeled cells. Animals that received only irradiation showed some increase in labeled cells per crypt above control levels; however, the proliferative response was not nearly of the magnitude of that observed in the DMH-irradiation group.

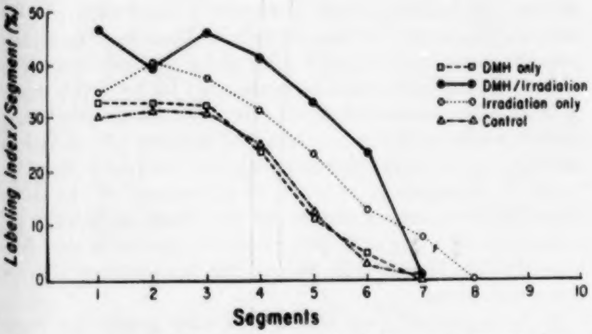


TEXT-FIGURE 1.—Comparison of the changes in the No. of cells/crypt over time in the treatment groups. *Each point* represents the mean value from 5 animals; *bracketed lines* represent the SE of the mean. *Arrows* along the *abscissa* indicate the times of irradiation. Irradiation appears not to affect the total No. of cells in mucosal glands of the mouse colon.

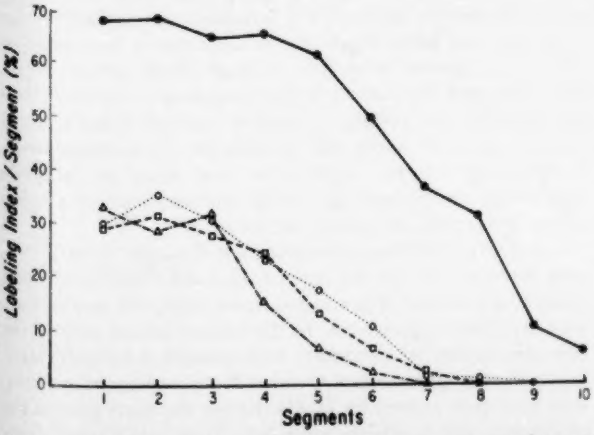


TEXT-FIGURE 2.—Comparison of the changes in the No. of labeled cells/crypt over time in the 4 treatment groups. Symbols are the same as in text-fig. 1. Irradiation dramatically increased the No. of labeled cells/crypt in animals that received DMH.

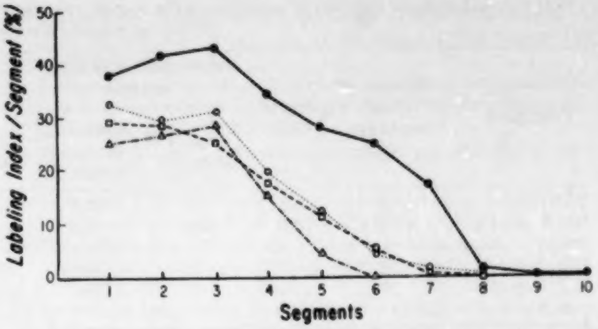
The distribution of labeled cells in crypts after DMH-irradiation treatment showed an increase of the labeling index of each segment and a marked shift of the labeled cells toward the surface. The proliferative zone expanded to include a larger proportion of the total crypt column (text-figs. 3–6). The largest change in the relative size of the proliferative zone occurred after 4 weeks of DMH treatment, when labeled cells appeared in all segments of the crypt column and on the surface epithelium. This pattern persisted after 8 and 16 weeks of DMH treatment, although the early effects of the irradiation became progressively less pronounced in these later groups.



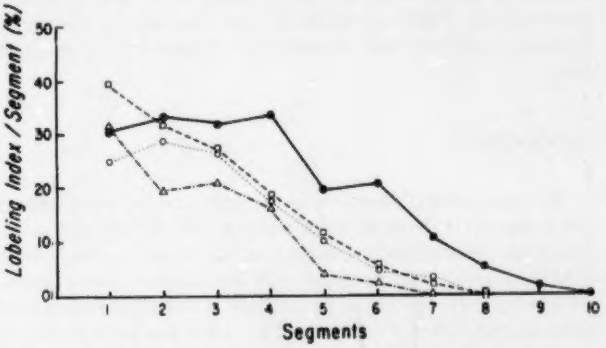
TEXT-FIGURE 3.—Comparison of the relative differences in distribution of labeled cells in mucosal glands 2 wk after the start of the experiment. *Each point* represents the mean percentage of labeled cells in 5 animals. The relative size of the proliferative zone increased groups that received DMH-irradiation. The overall mean No. of cells/crypt column/group of animals was divided into 10 equal segments. The percent labeled cells/segment was determined by the division of the No. of labeled cells/crypt segment by the total No. of cells/segment ×100.



TEXT-FIGURE 4.—Comparison of the relative differences in distribution of labeled cells in mucosal glands 4 wk after the start of the experiment. Symbols are the same as in text-fig. 3. The proliferative zone of the crypts of the DMH-irradiation group has expanded greatly.



TEXT-FIGURE 5.—Comparison of the relative differences in distribution of labeled cells in mucosal glands 8 wk after the start of the experiment. Symbols are the same as in text-fig. 3. Even though the proliferative zone of the crypts of the DMH-irradiation group is smaller than it was at 4 wk, it is still relatively larger than that of other groups.



TEXT-FIGURE 6.—Comparison of the relative differences in distribution of labeled cells in mucosal glands 16 wk after the start of the experiment. Symbols are the same as in text-fig. 3. The proliferative zone of the DMH-irradiation group has reduced in size even further; however, labeled cells were still found in the upper segment of the crypts in animals of this group.

In groups of animals that received irradiation only, we observed a similar but smaller cell proliferation response. Changes in number and distribution of proliferative cells in crypts were significantly different ($P<0.05$) from those of control animals 2 weeks after the first irradiation. However, at later treatments only the presence of a few labeled cells in crypt column segments close to the surface distinguished the animals that received irradiation alone from untreated controls.

Relative differences in the number of distinct lesions and the times of their appearance in the colonic mucosa of irradiated and nonirradiated animals treated with DMH are shown in table 1. The important difference between the groups was not the uniqueness of a particular lesion to a treatment, but that the overall level of mucosal transformation in nonirradiated animals was much greater than that in irradiated mice. The irradiated group had fewer tumors after 20 weeks of DMH treatment than the group that received DMH alone. Focal atypias were present in approximately the same proportion of animals in the 2 groups, but there were more focal atypias per animal in those that were not irradiated. In addition, microcarcinomas were present only in the nonirradiated group after 16 weeks of DMH treatment. Mice in the DMH-irradiation group developed about the same number of mucosal cysts compared to the number in nonirradiated animals that received DMH. The cysts usually formed in the base of the crypts, apparently as a consequence of disruption in the normal cell

Table 1.—*Histologic analysis of segments of the mid-descending colon of mice treated with DMH for 16 or 20 weeks and irradiated with 300 rad per mouse before weeks 1, 3, and 6 of treatment*[a]

Treatment	Duration of DMH treatment, wk	No. of mice	Abnormal crypts/focal atypias		Microcarcinomas		Cysts		Visible tumors	
			Total No. observed	Mice with at least 1 lesion, %	Total No. observed	Mice with at least 1 lesion, %	Total No. observed	Mice with at least 1 lesion, %	Total No. observed	Mice with at least 1 lesion, %
DMH only	16	10	30	100	3	30	8	70	—	—
DMH-irradiation	16	8	16	87.5	—	—	17	62.5	—	—
DMH only	20	16	70	100	11	56.2	22	68.7	18	63

[a] Abnormalities were recorded from representative step-serial sections. Two levels of the colon, separated by 300–500 μm, were analyzed. Types of lesions observed have been defined in the text.

organization in the upper regions of the glands. Finally, histologic differences in the mucosa were less apparent between the DMH-irradiation and DMH-only groups of animals that had been treated with DMH for 12 weeks or less.

DISCUSSION

We compared differences in the responses of crypt cells of the colon epithelium in mice treated with DMH and given low-dose, whole-body irradiation to those treated with DMH alone or that received only irradiation. The number of labeled cells per crypt in animals given DMH increased dramatically after irradiation. This surge has been shown to occur because the epithelium compensates for the induced loss of cells by increasing the proliferative activity in the remaining cells (*2*). The magnitude of compensation is a function of the level of cell depletion which, in turn, is related to the total dose and frequency of the irradiation (*1*). The radiation dose we used was sufficient to kill a proportion of the most susceptible target cells, the mitotic cells, but not large enough to kill many cells in other phases of the cell cycle more resistant to irradiation (*1*). In the irradiated tissue cellularity decreases as dead cells are removed, and repopulation begins only when damaged proliferative cells exhaust their limited division potential and undamaged stem cells begin to divide (*11*).

When groups given DMH for 3 weeks were irradiated, both the labeling index and the proliferation zone increased significantly to the extent that labeled cells were observed in the upper crypt segments and in the surface epithelium. In contrast, we observed a much lower response in animals that were irradiated but were not given DMH. These findings suggest that treatment with DMH accentuates the effect of irradiation by an increase of the number of target cells at risk to radiation and results in an amplification of the compensatory surge of the remaining proliferative cells. This amplification did not recur after the third irradiation, after 6 weeks of DMH treatment because DMH-induced changes in the cell population were reduced by the earlier sloughing of altered cells.

A surge in proliferation usually leads to an overshoot in the number of cells retained in the upper crypt and an enlargement of the overall size of the crypt (*12*). In the present model, [^{3}H]dThd-labeled cells were observed in high positions in the crypts after irradiation, because the proliferative zone had expanded. However, it is not clear why the increase in number of labeled cells did not lead to a comparable increase in the total number of cells per crypt. The increased labeling cannot be accounted for by DNA repair of irradiation-induced errors in the cells since these events usually occur within a few hours of damage (*3*). A lack of enlargement in crypt size suggests that long-term development of hyperplastic mucosa, characteristic of the colon after DMH treatment, results not only from increases in the number of dividing cells per crypt but also from modification of other factors that control the homeostasis of crypt cell populations.

In mice treated with DMH and then irradiated, fewer identifiable lesions of the colon developed than in DMH-treated unirradiated animals. Moreover, those lesions that were present required longer periods of time to develop. These observations indicate that irradiation in some way delays the transformation of the mucosa. Hamilton (*13*) has demonstrated that after a large single dose of radiation, the denuded crypts are regenerated from single clonogenic cells located in the upper region of the proliferative zone of the crypts. Evidently, any cell in this region can randomly revert to a stem cell from which the entire crypt is then repopulated. This pattern is unlikely to occur in the present experiment because the radiation dose was at a much lower level that enabled the animals to receive multiple doses and still survive up to 20 weeks post irradiation. As a consequence, repopulation of the crypts after low doses of radiation apparently results from an overall increased rate of division of the remaining mitotically active cells.

Currently, DMH carcinogenesis is thought to be a two-step process (*14*). In the first phase, each DMH treatment induces a number of pretransformed cells that accumulate with successive treatments. In the second phase, cells of the first population are randomly transformed, eventually leading to the development of tumors. A proportion of the cells, that were first altered by DMH during the early part of the treatment, are probably sloughed after irradiation. This results in an overall reduction in the relative transformation of the mucosa and ultimately decreases the number of tumors that develop in 20 weeks.

Tumor-Induced Neovascularization in the Mouse Eye[1,2,3]

V. R. Muthukkaruppan,[4] L. Kubai,[5] *and* R. Auerbach[5,6,7]

ABSTRACT—Tumor fragments implanted in the mouse cornea induce a neovascular reaction characterized by the penetration of new blood vessels into the avascular cornea that ultimately reach the tumor to permit its further rapid growth. A method to achieve angiogenesis in the mouse cornea was studied, as well as the histologic and gross manifestations of the neovascular reaction and the effect of tumor cells or host irradiation on the observed angiogenic response. Sequential stages of tumor-induced neovascularization are described and documented for sarcoma 180- and C755 mammary adenocarcinoma-induced angiogenesis. A number of distinct processes of the angiogenesis response to tumors are discussed which suggest that several families of angiogenesis-inducing factors may mediate each of these processes. The importance of the development of a mouse model for the study of angiogenesis is stressed.—JNCI 1982; 69:699–708.

Neovascularization is now recognized as a major component of a variety of disease processes ranging from lymphadenopathies to the development and spread of cancer. Its role in inflammatory reactions, in graft maintenance and rejection, and in delayed hypersensitivity is beginning to be more fully appreciated. The generation of new blood vessels, angiogenesis, has been studied in a variety of test systems (*1–3*). Aside from making direct observations in situ of growing tumors, of inflammatory lesions, or of capillary regeneration after injury, the principal approach has been to transplant angiogenesis-inducing tissues ectopically into a dorsal air sac of the rat, into the cheek pouch of hamsters, as grafts on the CAM of chick embryos, or into the adult mammalian avascular cornea. Efforts to obtain in vitro correlates of angiogenesis reactions have recently begun to show some success as well (*4, 5*). Both mitogenesis and cell migration of endothelial cells have been used in these in vitro test systems, but it is not yet clear how reliable as indicators of in vivo responses these cell culture systems will be. Because most in vitro tests have used endothelial cells from large vessels and because the measured responses are of quite general biologic reactions, continued reference to in vivo tests of angiogenesis is essential for studies of neovascularization.

Our research group has, over the past several years, begun to develop both in vivo and in vitro tests of angiogenesis that will permit the examination, under genetically controlled conditions, of the cellular and subcellular factors leading to angiogenesis. For this reason, we have concentrated on the development of techniques for studies of angiogenesis systems involving the mouse, since this species has major advantages through the extensive range of genetically characterized tumors, reagents for delineation, fine dissection of cell types on the basis of differentiation antigens, and genetically homogenous inbred lines and mutants that represent a wide range of disease models. Among the test systems we have developed are the LIA assay system involving the introduction of angiogenesis-inducing lymphocytes intradermally into syngeneic or allogeneic irradiated adult host animals (*6, 7*); xenogeneic assays in which murine effector cells, tissues, or extracts are placed on the CAM of explanted chick embryos (*8*); in vitro assays of mitogenesis and cell migration of mouse capillary endothelial cells (Joseph J, Form D, Watt S, Auerbach R: Unpublished observations); and the murine intracorneal assay in which angiogenesis-inducing tissues or slow release pellets are placed into an intrastromal corneal pocket of adult mice (*9*).

Of all the test systems for neovascular reactions, the intracorneal response is the most definitive, inasmuch as new blood vessels must penetrate an avascular space to reach the angiogenesis-inducing stimulus. Moreover, in contrast to the in vitro tests, the intracorneal response permits the assessment of systemic host factors that influence the progress of neovascularization. To permit the mouse corneal angiogenesis reaction to be used effectively for the analysis of the neovascular process, we now present a detailed description of the sequence of gross and histologic events that occur after the implantation of tumors into the cornea.

MATERIALS AND METHODS

Mice.—BALB/cAu, C57BL/6Au, and ICR/HaAu strains of mice were obtained from our own inbred mouse colony. For several experiments we used the C57BL/6c2J albino mutant and (BALB/cAu × 129/J)F_1 and (ICR/HaAu × C57BL/6c2J)F_1 hybrids. (BALB/cJ × A/J)F_1 (CAF_1) mice were obtained from The Jackson Laboratory, Bar Harbor, Maine.

Tumors.—The C755 mammary adenocarcinoma work was initiated with tumors obtained from Dr. Kelly Clifton,

We appreciate the administrative and editorial assistance of Barbara Houser, M.S., the help with photography of Gilbert Burns, Donald Chandler, Hilary French, and Laura Vanderpooeg, the assistance of Wanda Auerbach, M.L.S., and Bich Van Nguyen with literature retrieval, and the excellent animal care provided for our research animals by Patricia Cofta, Philip Corona, John Gundlach, Robert Peterson, and William Peterson. We appreciate the scientific discussions with our colleagues David Form, Ph.D., Jeymohan Joseph, M.S., and Younan A. Sidky, Ph.D. We thank Jacqueline Grieves and Gwendolyn Holbrow for technical assistance.

University of Wisconsin-Madison, which were subsequently maintained by subcutaneous passage in C57BL/6 mice. Subsequently, tumor morphology became somewhat atypical, and a new stock of C755 tumor was obtained from the tumor bank of the National Institutes of Health (Bethesda, Md.) and was maintained in similar fashion. The S180 studies in the present paper were done with the use of a tumor line maintained in vitro in Dulbecco's modified Eagle's minimum essential medium with fetal calf serum. Additional experiments, not included in the present study but with similar results, involved fresh S180 tumors obtained from the National Institutes of Health tumor bank and maintained either in BALB/c or in ICR/Ha mice.

Grafting procedures.—The intracorneal grafting method was one modified from that described by Gimbrone et al. (*10*) and outlined briefly in our earlier report (*9*). Mice were anesthesized with tribromoethanol (1:1 in tertiary amyl alcohol diluted 1:50 in 10% ethanol and administered as 0.01 ml/g body wt; Avertin). This anesthetic proved to be particularly useful since it was gentle, it did not lead to pupil dilation, and it was tolerated over a fairly wide dose range. If animals recovered from anesthesia before surgery could be completed, additional anesthetic could be administered safely. The eye was irrigated with antibiotics (500 U penicillin and 500 μg streptomycin/ml phosphate-buffered saline). A transverse 1-mm incision was made in the cornea with the use of a #65 Beaver blade (Beaver Instruments, Waltham, Mass.). The cut penetrated about halfway through the cornea, deep enough to permit insertion of a spatula, but not so deep as to penetrate the anterior chamber of the eye. The pocket was prepared with a malleable iris spatula (V. Mueller Co., Chicago, Ill.) ground down extensively to yield a fine, thin edge. The pocket was extended to reach within about 0.8 mm of the limbus. Tissue fragments (0.5 mm^3) were then inserted into the pocket by means of the same spatula. Tumor cells from culture were implanted with a small-bore (0.1–0.2 mm in inside diameter), orally controlled micropipette. The entire surgical procedure was performed by lighting supplied either by a Luxo surgical lamp cooled by light passage through a long plastic extension tube or by fiber optic illumination with additional heat-absorbing filters placed between the light source and the fiber extension tube. We found lighting to be critical, and the importance of cooling the light source cannot be overemphasized, since corneal damage can result from excessive heat and may lead to spurious neovascular reactions.

Preparation of material for examination.—Histologic preparations were made from Formalin- or Bouin's-fixed material embedded in paraffin, sectioned at 7 μm, and generally stained with hematoxylin and eosin. Other fixatives and stains were used for specific experimental purposes.

India ink perfusions were accomplished by retrograde injection of filtered Pelikan-brand india ink after extensive perfusion with 0.9% saline to clear erythrocytes from the circulation. After the ocular vasculature became filled with india ink, the eyes were bathed in 10% Formalin buffered at pH 7 and further fixed in Formalin, followed by clearance in 50% glycerin.

Photographs were taken with standard illumination on mildly anesthesized animals or with a flash attachment on unanesthesized animals. The mouse was held at a sharp enough angle to obtain corneal vascular images similar to those obtained by use of a slit lamp.

Other angiogenesis assays.—Intradermal neovascular responses were done as described previously (*6*). Test cell suspensions were inoculated into sublethally irradiated adult mice, with the amount of the intradermal inoculum held constant at 0.1 ml. The animals were killed 3 days later, a skin flap was opened up, and the extra blood vessels visible around the inoculation site were enumerated to obtain a measure of the vascular reaction.

Angiogenesis on the chick CAM was performed on embryos grown in petri dish culture (*11*). Eggs were incubated for 3.5 days, the egg contents were placed in 100-mm petri dishes, and the uncovered dish was placed inside a larger (150 mm) petri dish (covered) for humidification and incubation. Five days later grafts were made onto the CAM by means of a small incision into which the tissue to be tested was placed. Care was taken to ensure that the incision was small enough that the graft would not slip through the membrane. Neovascularization was monitored daily for 4-5 days.

RESULTS

Vascular Response in Control Grafts

Normal mammary gland tissue from nonlactating adult female C57BL/6 mice was implanted into the corneal stroma of syngeneic recipients to serve as a reasonably normal counterpart for the C755 mammary tumor. Additional control grafts were made with the use of inguinal and mesenteric lymph node fragments from syngeneic mice (table 1).

For 2 days after a pocket is made in the cornea, limbal activity can be observed. This activity is transient and vasodilatory in nature and disappears within 2 days after trauma. The grafting of normal mammary gland or syngeneic lymph node fragments causes no additional reaction. Carbon perfusion of corneas bearing mammary gland or syngeneic lymph node implants prepared several days after

TABLE 1.—*Tumor-induced angiogenesis in the mouse cornea*

Host strain	Source of graft	Total no. of grafts	No. of grafts with:		
			No growth	Growth	Angiogenesis
C57BL/6J	C57BL/6 mammary gland	4	4	0	0
	C57BL/6 lymph node	3	3	0	0
	C755 mammary adenocarcinoma	10	4	6	6

BALB/c	S180	12	0	12	12

grafting revealed the normal pattern of limbal blood vessels (fig. 1). Opacity, corneal edema, or other signs of an inflammatory reaction were almost universally absent, being observed in fewer than 5% of the corneal grafts prepared in our laboratory. We routinely exclude those implants (corneal and experimental) that show a broad inflammatory reaction within the first 2 days; such reactions generally accompany infection.

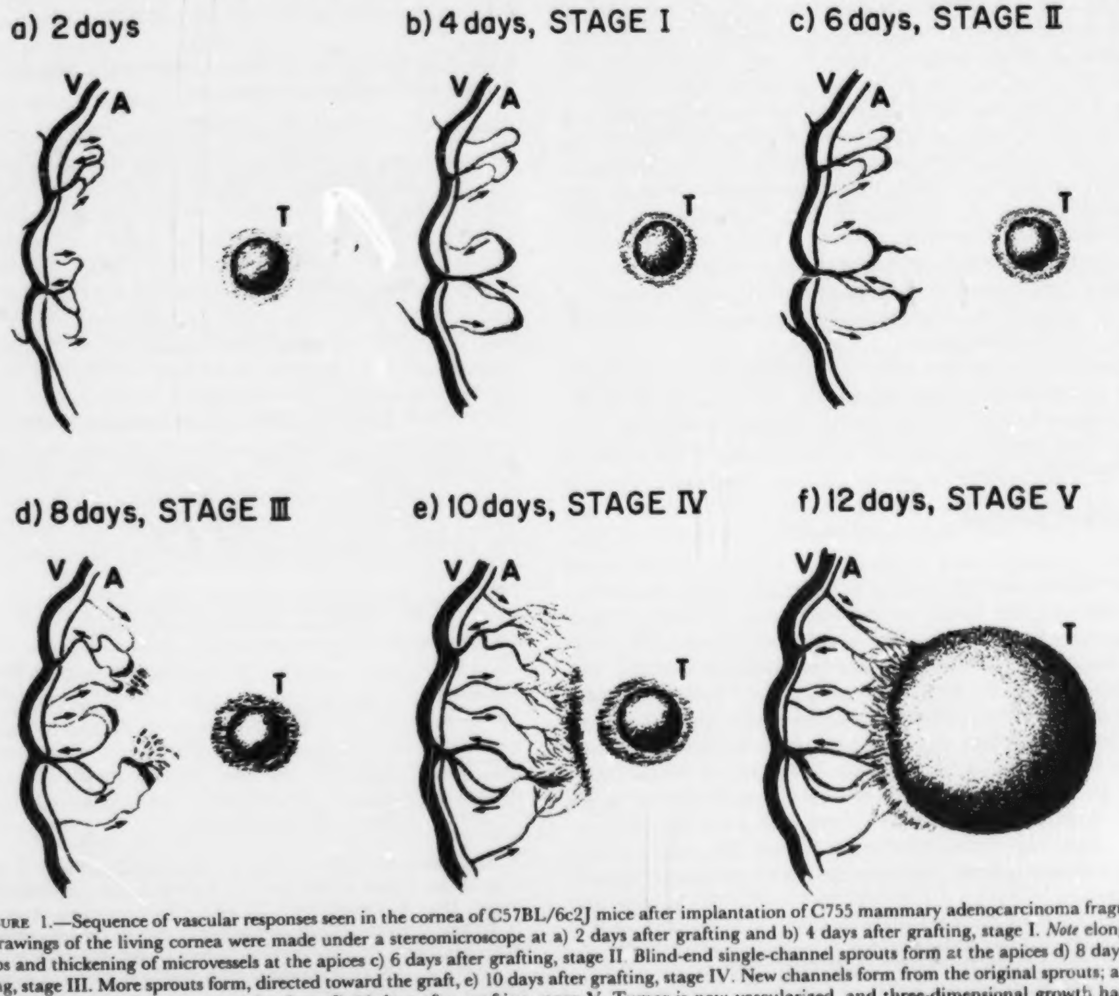
Tumor-Induced Angiogenesis

To determine the extent and nature of angiogenesis induced by various tumors, we selected the C755 mammary adenocarcinoma and the S180 as primary tumor types. C755 grows only in C57BL/6 or F_1 hybrids derived from this strain of mice. Conversely, S180 grows rapidly in all the strains we tested, although we generally used mice that carried the histocompatibility genes ($H\text{-}2^d$) of the strain of tumor origin (BALB/c or F_1 animals which included BALB/c as one of the parents). The C755 tumor was originally transplanted into black mice, but subsequently we used congenic C57BL/6c2J albino mice to facilitate making in situ observations of the graft and the vascular response.

Of 28 C755 tumor grafts implanted into syngeneic animals, 20 induced angiogenesis, and in these cases tumor growth was consistently observed (table 1; fig. 2). S180 induced vascularization and developed as growing tumor masses in all 12 of the grafts made (table 1). In all instances, vessel outgrowth began in the limbal region most directly apposed to the edge of the corneal pocket, and the progress of vessel penetration into the cornea could be monitored by daily measurements with an ocular micrometer.

Sequence of Tumor-Induced Vascular Events

Several corneas bearing tumor implants were monitored critically by sequential photographs as well as by routine measurements. One representative series obtained with a C755 tumor graft is shown in text-figure 1. Whereas the



TEXT-FIGURE 1.—Sequence of vascular responses seen in the cornea of C57BL/6c2J mice after implantation of C755 mammary adenocarcinoma fragments. The drawings of the living cornea were made under a stereomicroscope at a) 2 days after grafting and b) 4 days after grafting, stage I. *Note* elongation of loops and thickening of microvessels at the apices c) 6 days after grafting, stage II. Blind-end single-channel sprouts form at the apices d) 8 days after grafting, stage III. More sprouts form, directed toward the graft, e) 10 days after grafting, stage IV. New channels form from the original sprouts; a brush border is seen at the advancing vascular front f) 14 days after grafting, stage V. Tumor is now vascularized, and three-dimensional growth has been initiated. Each of the stages has also been identified with carbon-perfused corneal preparations. For comparison with S180 grown in BALB/c mice, *see* table 3. V=vein; T=tumor; A=artery.

initial limbal activity in the control cornea subsided within 2 days, the tumor-bearing cornea exhibited elongation of the initial loops as much as 0.4 mm from the limbal vessels toward the tumor by day 4 (text-fig. 1a, 1b). We consider tumor-induced angiogenesis to be initiated after 2 days only and classify the response seen by day 4 as stage I, with the recognition that events in the first 48 hours may also be tumor-specific but may simply be masked from characterization by virtue of the general limbal response to preparation of the pocket.

In stage I, the apices of the vascular loops appeared thicker than the remaining parts of the microvasculature (text-fig. 1b). The vascular loops were intact, allowing normal blood flow from the arteriole to the venule of the limbus to continue. At this point, the tumor implant appeared to have spread slightly from the original pocket.

By day 6, single blind-end channels or sprouts developed from the apices of the loops toward the tumor implant, and blood flow was sluggish in these sprouts in contrast to the original loops where circulation remained normal (stage II; text-fig. 1c). This event was soon followed by the formation of more such sprouts that lengthened with their tips directed toward the graft (stage III; text-fig. 1d). Shortly after this time the proximal ends of the sprouts showed normal blood flow from the loops, and the distal tips were all arranged in a row, thus giving the appearance of a brush border of red blood cells in the living cornea (stage IV; text-fig. 1e; fig. 3). Within the next 2-4 days, the tumor implant became vascularized (stage V; text-fig. 1f; fig. 4), leading to rapid, three-dimensional growth, corneal bulging, and ultimately exophytic progress of the tumor. Carbon-perfused preparations of tumor-bearing corneas provided clear documentation of each of the stages described by sequential observations on individual grafts.

Vascular events seen after the implantation of S180 tumors were similar, even though the timing was different. S180 tumors could induce sprout formation as early as 3 days after grafting, and the implants generally became vascularized by day 8.

Histologic Studies

The growing tumor implant was initially found to be contained within the corneal stroma, and both epithelium and endothelium of the cornea were intact. Until the new vessels penetrated the tumor, growth remained effectively two dimensional. After the new microvessels reached the tumor, a number of blood vessels could be seen in and around the graft, and the center of the tumor mass appeared necrotic by the time the corneal surface became ruptured due to the exophytic development of the tumor. At the zone between the limbus and the tumor implant, several large blood vessels could be seen in the stroma, most of them being distributed toward the epithelial side (figs. 5, 6). Inflammatory infiltration of leukocytes was conspicuously absent.

Allogeneic Tumor-Induced Angiogenesis

The mouse cornea model was used to analyze the nature of tumor-induced vascular responses in allogeneic tumor-host combinations. C755 mammary tumor cells (C57BL/6, $H\text{-}2^b$ origin) were grafted into the corneas of BALB/c ($H\text{-}2^d$) animals. Of 14 tumor grafts, 13 induced angiogenesis and became vascularized by day 13. The kinetics of the angiogenic response from stages I to IV was similar to that seen in syngeneic grafts. A major difference in the response was seen first in the fact that the typical brush borders of stages IV and V did not develop. The vessels in the tumor implant consisted mainly of vascular loops of a nonleaky nature, and extravasation of red blood cells was not observed. Though vascularized, tumors did not continue to grow and by day 17 appeared necrotic. However, the original vascular loops persisted with intact blood flow for several more days, regressing only at about the 25th day after grafting of the tumor.

Histologic analysis revealed an accumulation of lymphocytes around the tumor and the blood vessels in the stroma and in the limbus region (fig. 7). At that time (day 10), the tumor cells appeared viable, and several large blood vessels could be seen in the stroma around the graft. Tumor cell destruction occurred over the next several days.

Effect of Depletion of Host Lymphoid Cells on Tumor-Induced Angiogenesis

Insofar as the experiments involving allogeneic tumors demonstrated that host lymphoid cells were associated with the rejection of tumor allografts seen following tumor vascularization in the cornea, we believed it important to analyze the role that lymphocytes might play in the initial vascularization process as well, apart from allogenetically induced responses. We therefore examined the effect of host lymphocytes on a tumor that was histocompatible with the host and that also had been described as being of low immunogenicity, growing well in a number of unrelated murine strains. We selected S180 (BALB/c origin) and used (BALB/c × 129/J)F_1 hosts for these experiments. Tumors were implanted into hosts shortly after a sublethal dose (550 R) of total-body X-rays was delivered to these mice. The results (table 2), indicate that the tumor grafts were vascularized equally well in both irradiated and control mice. The initial vascular response in irradiated hosts was different

TABLE 2.—*Effect of sublethal irradiation of host mice on tumor-induced angiogenesis*

Irradiation,[a] R	Additional treatment[b]	No. of grafts made[c]	No. of tumors becoming vascularized[d]

[a] Cultures of S180 were irradiated from a gamma (cesium) source before intracorneal grafting into BALB/c mice.

[b] Remaining grafts had not progressed beyond loop formation at this time.

[c] Although the tumors were vascularized, the number of sprouts were reduced and the typical brush border effect was not seen. The remaining grafts failed to become vascularized.

to the extent that a general increased vasodilation and limbal activity were seen in the first few days after irradiation. The localized vascular outgrowth and penetration toward the pocket containing the tumor graft were visibly greater in irradiated animals, but the timing was comparable. It is likely that the increased visibility of the neovasculature was due to vasodilation and altered blood flow characteristics rather than to any basic alteration in the angiogenesis reaction itself. At any rate, there was no indication of a diminished angiogenesis response in hosts irradiated sufficiently to lead to a 90–95% reduction in circulating leukocyte levels (data not shown).

To be certain that the neovascular response we observed was similar because of offsetting effects of irradiation on the endothelial cells and on leukocyte levels, we performed reconstitution experiments by reinjecting syngeneic spleen cells into irradiated hosts prior to implantation of tumor fragments (table 2). The addition of unirradiated leukocytes to the irradiated hosts did not alter the timing or extent of the neovascular reaction.

Angiogenesis Induced by Irradiated Tumor Cells

To analyze the nature and extent of neovascularization induced by heavily irradiated tumor cells, we exposed S180 tumors to either 2,000 or 4,000 rad γ-irradiation from a cesium source immediately before they were grafted. As shown in table 3, the extent of induced loop formation was similar for irradiated and unirradiated tumors. However, the effect of irradiation was readily apparent for the later stages of vascularization. The number of vascular sprouts was greatly reduced, especially in the group exposed to 4,000 rad. The brush border effect typically accompanied by extravasation of erythrocytes was uniformly absent (fig. 8). Even though the irradiated tumor implants could become vascularized, tumor growth was not observed, which suggests that the irradiation had effectively blocked tumor cell replication.

DISCUSSION

Our description of the events accompanying neovascularization of tumor grafts placed in the corneas of adult mice is basically similar to that provided for the angiogenesis response previously documented for the rabbit (*10*). In both systems an implant of angiogenesis-inducing tissue can evoke vascular outgrowth from the limbal vessels into the avascular cornea, and in both instances the growth of tumors becomes rapid and three dimensional only after the blood vessels have penetrated the grafted tumor.

The delineation of reasonably distinct phases in the angiogenesis response not only provides a convenient set of markers for the process of vessel formation in response to grafting but also reflects the rather separate events that accompany the reaction. Initial activity of the limbal region is transient for control tissues or simple surgical manipulation alone. However, in the presence of angiogenesis-inducing stimuli, elongation of capillary loops occurs over the control level. Such activity may be an essential first step that must take place as a prelude to the later events of vascular penetration and endothelial cell migration and proliferation.

Loop formation and capillary sprouting appear to be distinct entities, and differences in vascular permeability (Muthukkaruppan VR, Auerbach R: Unpublished observations) at points along the new vessels (loop region vs. brush border region) suggest yet a third separate manifestation of the response. The extravasation of red blood cells and of injected carbon particles at the brush border was found to be characteristic of tumor-induced angiogenesis; however, the tight junctions between endothelial cells appear to be normal, as revealed by electron microscopic analysis (Clark AW, Muthukkaruppan VR: Unpublished observations).

It seems quite likely that the induction of angiogenesis involves several, not necessarily related, effector mechanisms. Factors that stimulate vasodilation, cell migration, loop formation (which is itself possibly a manifestation of migration), endothelial cell proliferation (both proximal in the limbal region and distal at the brush border form of the new microvessels), and changes in vascular permeability may all play a significant part in leading to the extensive vascular reaction associated with tumor growth (*1, 10, 12*).

The dissociation of some of these factors has already been suggested by our earlier observation that LIA can elicit vascular loops but apparently fails to yield a brush-border-type advancing sprouting edge (*9, 13, 14*). It is interesting in this regard that irradiated tumors as well as tumors placed in immunologically inhospitable environments fail to lead to the formation of this active advancing edge of the new capillaries. In this connection, the published figures of Folkman and his associates (*15, 16*) suggest that in the presence of cartilage-derived angiogenesis inhibitor, vascular loops are formed but sprouts appear to be absent and that already existing sprouts disappear from the cornea soon after removal of an angiogenesis-inducing stimulus (tumor angiogenesis factor in ethyl vinylacetate copolymer) from the corneal pocket, whereas the residual capillary loops remain for extended periods (*17*).

Further support for several discrete mechanisms for action of mediators of neovascularization comes from the fact that the isolation of angiogenesis-inducing chemical factors appears to have led to several distinct classes of factors, some of low molecular weight (prostaglandin-type), some macromolecular (growth factor types such as fibroblast growth factor or epidermal growth factor), and some in the general group of vasoactive mediators (e.g., heparin). The question of angiogenesis-inducing factors has been discussed in detail in a recent review (*3*) which can be consulted for detailed documentation and literature citations.

The ability of irradiated tumors to elicit angiogenesis in our experiments confirms for the mouse system what we have previously reported for tumor grafts placed on the CAM or in rabbit eyes (*18*). Irradiation also fails to prevent the initial neovascular reactions seen after intradermal inoculation of angiogenesis-stimulating allogeneic lymphocytes (*6*) or tumor cell suspensions (data not shown). It may be significant, however, that the extraction of tumor angiogenesis factor from irradiated tumor cell cultures by Folkman and his associates (*18*) appears to yield an active nondialyzable factor that is larger than the factor obtained by Weiss and her colleagues (*19*), who, using unirradiated tumors, report isolation of a smaller, dialyzable material (*3*). Our own observations on prostaglandin-associated angiogenesis (*20, 21*) as well as on the effects of prostaglandin synthetase inhibitors such as indomethacin (Sidky YA, Form OM, Auerbach R: Unpublished observations) suggest that the prostaglandin-associated angiogenesis effect may include stimulation of endothelial cell proliferation.

Form and Auerbach (submitted for publication) have proposed that since the amount of prostaglandin E_2 necessary to induce angiogenesis on the CAM is as little as 0.2 ng/day in their experiments—an amount less than the amount known to be released by activated macrophages or by many tumors and less than the amount reported to be present in inflammatory exudates or synovial fluids—this mediator alone may be adequate for initiation of angiogenesis in a variety of known biologic systems. An additional role of vasoactive factors released from mast cells (*22*) may provide further stimulation. It would be most attractive if the two factors acted synergistically, one inducing proliferation and the other inducing migration of endothelial cells. The perhaps special ability of tumors to further enhance the angiogenesis response may reflect action of yet a third class of agents, able to cause dissolution or perturbation of the growing edge of the capillary loops, leading to the observed brush border morphology and extensive capillary sprouting. It is in this phase of angiogenesis that the larger, tumor-associated, perhaps enzymatically active angiogenesis factors may be of major importance.

The use of mouse assay systems for the analysis of the angiogenesis reaction is clearly of major advantage for numerous reasons. Even with the use of the intradermal test assay system we have already been able to address such questions as assessment of the role of various subsets of the *H-2* complex in LIA, the effect of host T-cell deficiency (*nu/nu* athymic animals) on neovascular reactions, and the efficacy of T-cell subsets (Lyt antigens) in inducing LIA (*7, 23*). The availability of mutants of strains high or deficient in natural cytotoxic activities, of lines susceptible to the induction of tumors, and of inbred lines capable of sustaining growth of so many well-characterized tumor cell lines and the broad range of reagents developed especially for murine systems (e.g., antibodies directed against differentiation antigens and tumor-specific antigens) make mouse models most attractive. The availability, therefore, of an in vivo test system for angiogenesis in the mouse that can clearly distinguish between neovascularization and other vascular events, permits continued in situ observations without anesthesia, can be performed on large numbers of animals, and can be done with predictability should facilitate study of induced vascular reactions.

In Vitro Infection of Lymphocytes With Marek's Disease Virus[1,2,3]

Bruce W. Calnek,[4] Karel A. Schat,[4] William R. Shek,[4] *and* **Chen-Lo H. Chen[5,6]**

ABSTRACT—Suspension cultures of splenic lymphocytes, incubated at 41°C, became infected with Marek's disease virus (MDV) following exposure to *a*) other infected lymphocytes, *b*) infected chicken kidney monolayer cultures, or *c*) cell-free MDV. Both viral antigen expression and virus isolation could be demonstrated after more than 40 passages made by the addition of fresh spleen cells at 2- to 3-day intervals. Susceptibility of spleen cells from bursectomized chickens was markedly lower than that of cells from intact birds. Furthermore, when spleen cell suspensions were depleted of cells having characteristics of bursa-derived cells, e.g., those with surface IgM, Fc receptors, or ability to adhere to nylon wool, the susceptibility of the cell suspension was diminished. Enrichment of the suspension with cells having those features enhanced overall susceptibility. The target cells for virus infection in vitro also were shown to be nonphagocytic, to be of low or medium density, and to bear Ia-like antigen. In vitro susceptibility to infection of spleen cells did not correlate with the genetic susceptibility of the donor to Marek's disease.—JNCI 1982; 69:709–713.

MD, a naturally occurring lymphomatous disease of fowl, is caused by a cell-associated herpesvirus which may be isolated from latently infected lymphocytes by cocultivation with susceptible cell cultures such as CK monolayers (*1*). In vivo, the infection is biphasic, causing a cytolytic infection in lymphoid organs such as the spleen, thymus, and bursa of Fabricius during the 1st week, followed by a predominantly latent infection of lymphocytes thereafter. Lymphomas, which subsequently develop in a variable proportion of genetically susceptible chickens, are the result of neoplastic transformation of thymus-derived (T)-lymphocytes (*1*). Both T- and bursa-derived (B)-lymphocytes were reported to be involved in latent infections (*2*).

It was postulated that various subpopulations of lymphocytes were the targets of the different types of infection with MDV, i.e., cytolytic (productive-restrictive), latent, transforming (*1*). We (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication) have now obtained very substantial evidence that different subpopulations are involved. A very significant finding was that B-cells are the primary target of the early cytolytic infection, whereas the latent infection is largely associated with non-B-lymphocytes. These studies were conducted by the fractionation of cells infected in vivo.

In vivo infection patterns are probably influenced by a great many pathogenetic complexities in addition to the inherent susceptibility of various cell populations. In an effort to obviate that problem, we attempted to infect chicken lymphocytes in vitro where direct exposure of various cell types could be used to assess their susceptibility and response to MDV. This paper demonstrates that lymphocyte infection does occur following in vitro exposure to virus and that infection spreads among lymphocytes under culture conditions. Furthermore, we corroborate the conclusions of the in vivo studies by showing that B-cells are a major target of cytolytic infection in vitro.

MATERIALS AND METHODS

Viruses.—JM-10 and GA-5 clones of MDV have been described (*3*) and were used as cell-associated inocula consisting of infected CK cells from infected monolayer cultures or spleen cells from infected birds. Cell-free JM strain MDV was prepared as a skin extract (*4*) from chickens infected with uncloned virus.

Experimental birds.—Specific-pathogen-free chickens from departmental flocks of P-2, N-2, UCD-003, PDRC, and S-strain genetic lines were the sources of lymphocytes for in vitro infection studies. The P-2, N-2, and UCD-003 lines were, respectively, homozygous for the major histocompatibility alleles $B^{19}B^{19}$, $B^{21}B^{21}$, and $B^{17}B^{17}$ (*5, 6*); PDRC (*7*) and S-strain (*8*) birds are uncharacterized for these alleles. P-2 and S-strain chickens are genetically highly susceptible to MD, and the N-2 strain is highly resistant to MD; the susceptibility of UCD-003 and PDRC to MD is intermediate (*6*). Chickens that were donors of spleens, thymuses, or bursas of Fabricius were 2–4 weeks old.

For some experiments, PDRC or P-2 donors of spleen cells were EBx on the 17th day of incubation as described elsewhere (*9*). The efficacy of the treatment was assessed by examination of spleen cells for the presence of surface IgM in an indirect immunofluorescence test with mouse monoclonal anti-chicken IgM (μ-chain). This reagent is described elsewhere (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication). For some experiments, 3- to 4-week-old P-2 and N-2 birds, infected 5–13 days earlier with JM-10 or GA-5 virus, were donors of infected spleen cells. In one trial, spleen cells from two 5-week-old turkeys were compared with chicken spleen cells. These turkeys were

hatched and raised in isolation and were known to be free of turkey herpesvirus (*10*) and MDV infections.

Preparation of cells for in vitro studies.—Spleens, bursas of Fabricius, and thymuses were collected aseptically and gently forced through an autoclavable 60-μm mesh (Tetko Inc., Elmsford, N.Y.). Cells were suspended in phosphate-buffered saline (pH 7.3) and centrifuged over Ficoll–Paque (Pharmacia, Inc., Piscataway, N.J.). Lymphocytes, collected from the interface, were washed once and resuspended in LM-Hahn medium (*11*) at a concentration of $2\text{–}3\times10^6$/ml.

For some studies spleen cells were fractionated into subpopulations by procedures described in detail elsewhere (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication). Leukocytes were isopyknically separated by flotation in continuous Percoll (Pharmacia Chemicals AB, Uppsala, Sweden) gradients. Adherent cells were depleted with nylon wool or carbonyl iron (Sigma Chemical Co., St. Louis, Mo.). Cells with Fc receptors were separated from those without Fc receptors by adherence to chicken IgG-coated SRBC monolayers. We separated B-cells from non-B-cells by mixing SRBC coated with *Staphylococcus* protein A (Pharmacia Chemicals AB) with spleen cell suspensions pretreated with mouse monoclonal IgG (Y2b) anti-chicken IgM. The B-cell rosettes that formed were separated from the nonrosetted cells by centrifugation over Ficoll–Paque. Cells bearing Ia-like antigen were eliminated by lysis with mouse monoclonal IgM (uK) anti-chicken Ia and guinea pig complement.

In vitro infection and culture conditions.—Lymphocytes to be exposed to MDV were suspended in LM-Hahn medium, counted in a hemacytometer, and adjusted to a concentration of $2\text{–}3\times10^6$ viable cells (on the basis of trypan blue dye exclusion)/ml. MDV exposure was effected by cocultivation with infected lymphocytes or infected CK monolayers or by the addition of cell-free virus to the lymphocyte suspension. Infected lymphocyte inocula consisted of *a*) primary cultures of spleen cells obtained from infected chickens prepared as above and incubated at 41°C for 48 hours or *b*) 48-hour spleen cell cultures representing up to the 43d serial passage. The ratio of infected to uninfected cells was from 1:1 to 1:7. For exposure to infected CK cells, lymphocyte suspensions were added to heavily infected (>50% cytopathic effect) CK monolayers at the rate of 5 ml/60-mm petri dish culture. The lymphocytes were washed off after incubation at 41°C for 24–48 hours. Cell-free virus, with a titer of about 3,000 PFU/ml, was added to lymphocyte suspensions at a ratio of 1:10 (vol/vol).

All lymphocyte cultures consisted of 2 ml per plastic tube (#2057; Falcon Plastics, Oxnard, Calif.). Caps were left loose, and incubation was at 41°C in a humidified atmosphere of 5% CO_2 in air.

Serial passages of MDV infection in spleen cells were performed by the addition of freshly prepared uninfected spleen cells to an infected culture at 2- to 3-day intervals. Generally, the ratio of fresh to infected cells was 3:1. With few exceptions, passages were done with cells from P-2 chickens.

Tests for infected cells in cultures.—Virus isolations were performed by inoculation of 0.5 ml of cultured lymphocyte suspensions onto primary CK monolayers in 35-mm plastic petri dishes. The number of PFU was determined 6 or 7 days later and recorded in terms of PFU/ml.

The number of cells per milliliter expressing VIA was determined as described elsewhere (*11*). The lymphocyte suspension was concentrated ten times by centrifugation and resuspension in phosphate-buffered saline, and 10-μl drop smears were air dried on glass slides. Acetone-fixed smears were stained with fluorescein isothiocyanate-conjugated MDV antibodies, and the number of positive cells was enumerated with epi-illumination with the use of a Leitz Dialux fluorescence microscope. VIA-positive cells were recorded as the number positive per milliliter.

Statistical analyses.—Data were compared with the use of Student's *t*-test (*12*).

RESULTS

General Characteristics of In Vitro Infection and Passage of Virus in Splenic Lymphocytes

Table 1 contains data from representative trials that illustrate the successful infection and passage of virus in suspension cultures of splenic lymphocytes. Infection could be initiated with cell-free virus as well as with cell-associated virus from cultured CK cells or spleen cells from infected birds. VIA expression rates exceeded virus isolation rates by a substantial margin (up to 3 $\log_{10}$) in most instances when parallel assays were done. This observation is similar to earlier observations on virus genome expression in vitro (*2, 11*). VIA was detected in both the nucleus and cytoplasm of cells stained in immunofluorescence tests.

The number of positive cells per milliliter increased sub-

TABLE 1.—*Serial passage of MDV in cultured spleen cells from P-2 chickens*[a]

Spleen cell culture passage No.	No. of cells positive, $\log_{10}$/ml for VIA or virus isolation (PFU)[b]

1	3.2	3.4 (1.9)	ND	0
2	1.8	2.7 (1.0)	ND	1.6 (1.7)
3	1.8	3.1 (0.1)	3.2	1.9
4	3.3 (1.4)	3.6 (1.4)	3.0	1.8
5	3.5	3.4 (2.9)	2.9	2.3
6	3.9	ND	3.9	3.6
7	3.9	ND	ND	ND
8	3.8 (1.3)	ND	ND	ND
35	ND	4.3 (2.1)	ND	4.2 (2.2)
43	3.7 (2.0)	ND	ND	ND

[a] Passages were made every 2–3 days by addition of freshly prepared spleen cells at a concentration of $2\text{–}3\times10^6$/ml. Ratio of fresh to infected culture cells was 1:1–3:1. Inocula incubated without addition of fresh spleen cells were all negative for VIA or infectivity by 3–4 passages. ND = not done.

[b] Smears to detect VIA by immunofluorescence or virus isolations to assay PFU were done at 48 hr after passage.

[c] Cells (2×10^6/ml) were cultured at 41°C for 2 days before use as inoculum.

[d] Passage 1 was done by the addition of spleen cells to infected monolayers; the spleen cells were washed off 48 hr later.

stantially between days 1 and 2 after inoculation, but not thereafter. Both VIA expression and virus isolation rates were higher with incubation at 41°C than at 37°C. As previously noted (*2*), the viability of cultured lymphocytes dropped rapidly, so that generally less than 10% of the lymphocytes were alive after 72 hours of incubation. Thus passages were more successful when done at 2-day intervals than at 3- or 4-day intervals. Removal of dead cells by centrifugation over Ficoll–Paque reduced the number of VIA-positive cells by 65–70%. Two trials were done to determine if cell-to-cell transfer of MDV required shared major histocompatibility antigens or if the rate of virus infection was influenced by the genetic constitution of the spleen cell donors. The results, summarized in table 2, show that there was no allogeneic restriction; levels of infection were as high or higher in histoincompatible cells as in histocompatible cells. Furthermore, it was clear that susceptibility of lymphocytes to in vitro infection from infected cultured spleen cells did not follow the pattern of genetic susceptibility to tumor development seen in the various chicken strains. In fact, cells from the most resistant donors (N-2) showed the highest (albeit not significant) level of in vitro infection, whereas the UCD-003 strain, in which donors are of intermediate susceptibility to MD, had the lowest ($P<0.005$). In other trials, continued serial passage of GA-5 or JM-10 virus in parallel in P-2 or N-2 spleen cell cultures resulted in essentially identical titers as determined by VIA expression and virus isolations.

Characterization of Target Cells

We conducted several experiments to identify the cell type(s) susceptible to in vitro infection with MDV. In the first experiment, spleen cells from P-2 chickens were fractionated by methods found to be useful in identifying types of infected cells in vivo (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication). Data recorded in table 3 characterized the susceptible cell population(s) as being of low or medium density, readily adherent to nylon wool, and refractory to removal attempts with carbonyl iron. Furthermore, the susceptible cells had Fc receptors and surface IgM.

TABLE 2.—*Effect of genetic strain on susceptibility of spleen cells to in vitro infection with MDV*

Spleen cells exposed in vitro[a]	VIA-positive cells/ml				
	Trial 1: Inocula = spleen cells 5 days post inoculation from individual GA-5-infected birds[b]				Trial 2: Inoculum = 35th passage JM-10 in P-2 spleen cells[c]
	P-2 #1	P-2 #2	N-2 #1	N-2 #2

Depletion by carbonyl iron	Depleted	1,030±258*
	Nondepleted	1,233±209*

[a] Inoculum = 48-hr culture of the 21st serial passage of GA-5 virus in P-2 spleen cell cultures. Four passages were made at 2-day intervals by the addition of 3 parts of freshly fractionated cells from uninfected P-2 spleens to 1 part of infected cultured cells.

[b] Means were based on 8 samples; there were 2 replicates for each passage (4 samples; 1 each passage for rosetted fractions). *Means followed by same superscript symbol* within groups were not significantly different ($P>0.05$, Student's *t*-test).

Three trials in the second experiment (table 4) showed that the target cells for MDV infection bore Ia-like antigens on their membranes since depletion of Ia-bearing cells by complement lysis with mouse monoclonal anti-Ia reduced the susceptibility of spleen cell suspensions in which MDV was serially passaged four times.

Two trials were conducted to determine the relative susceptibility of spleen cells from EBx versus intact donors (table 5). Within each trial the donors were from the same

TABLE 4.—*Effect of complement lysis with anti-Ia on the susceptibility of P-2 spleen cells to in vitro infection with MDV*

Trial[a]	Treatment of spleen cells for passage[b]	VIA-positive cells/ml at 48 hr after passage			
		Passage 1	Passage 2	Passage 3	Passage 4
1	C alone	2,180	460	100	480
	C + anti-Ia	570	270	30	0
2	C alone	220	60	200	1,360
	C + anti-Ia	110	140	20	30
3	C alone	3,060	1,880	2,880	2,560
	C + anti-Ia	1,630	270	80	120

[a] Inocula for trials 1 and 2 were individual MDV-infected spleen cell suspensions from GA-5-infected P-2 chickens; inoculum for trial 3 was 48-hr 4th passage of GA-5 virus-infected P-2 spleen cells.

[b] Uninfected, freshly prepared spleen cells were treated with complement (C) alone or C plus monoclonal anti-Ia and then were added to inoculum (passage 1) or to 48-hr cultures (passages 2–4) at a ratio of 1:1 (trials 1 and 2) or 3:1 (trial 3). All suspensions were at 3×10^6 cells/ml.

TABLE 5.—*Comparative susceptibility of lymphocytes from bursa of Fabricius, thymus, or spleen of intact or EBx chickens or turkeys to in vitro infection with MDV*

Trial	Lymphocyte source		No. of samples	Positive cells/ml 48 hr after inoculation with MDV-infected cultured spleen cells, means ± SEM[a]	
	Bird	Tissue		VIA	PFU
1	P-2	Spleen	4	9,065±690*	181±21*
	EBx P-2	Spleen	6	1,230±344†	83±9†
	Turkey	Spleen	2	320±100‡	0‡
2	(Inoculum control)		3	217±22*	
	PDRC	Spleen	3	1,003±152†	
	EBx PDRC	Spleen	3	217±52*	
3	(Inoculum control)		4	225±18*	
	P-2	Spleen	4	2,110±572†	
	P-2	Bursa	4	798±384*†	
	P-2	Thymus	4	683±243*†	

[a] Inocula were added to fresh lymphocytes at a ratio of 1:3. Infected cells were from 21st to 43d passages of JM-1C or GA-5 in P-2 cells. *Means followed by same superscript symbol* were not significantly different ($P>0.05$, Student's *t*-test).

hatch. In trial 1, turkey spleen cells were also compared to spleen cells from intact or EBx P-2 chickens. The number of VIA-positive cells in the turkey cell culture after 48 hours was approximately that expected from the inoculum cells alone (as in trials 2 and 3) and virus could not be isolated; thus the turkey cells were considered refractory to infection. In contrast, the spleen cells from EBx donors in that trial showed evidence of susceptibility when these cells were compared with the turkey spleen cells ($P<0.05$), but at a markedly reduced level when compared to the level found in the cells from intact donors ($P<0.05$). However, in trial 2, spleen cells from 3 EBx donors failed to evidence even a low level of susceptibility. The percentage of spleen cells of trial 1 birds that could be shown by immunofluorescence to have surface IgM was determined for the 4 intact and 6 EBx chickens. The respective means ± SE were 28.86±3.17 and 1.58±0.39 ($P<0.001$). Only 2 of the 6 EBx donor spleens had more than 1% positive cells (1.33 and 6.31), whereas all intact donor spleens had over 20% positive cells. The VIA and virus isolation rates from EBx donor spleen cell cultures did not appear to correlate with the percentage of IgM-bearing cells.

In the final trial (table 5, trial 3), lymphocytes from the spleens, thymuses, and bursas of Fabricius of 4 P-2 donor birds were compared. The number of VIA-positive cells in bursa or thymus cell cultures was in each case less than that in the spleen cell culture. Viability of bursa cells dropped much more rapidly than that of either spleen or thymus cells. Because of the short viability period of bursa cells in vitro, the data on the relative susceptibility to in vitro infection of these cells compared to spleen cells are not considered to be meaningful. Conversely, the viability of thymus cells in vitro was equivalent to that of spleen cells, and therefore the susceptibility of these cells to in vitro infection could be compared. The data comparing VIA expression by spleen and thymus cells in table 5 are from the first of three serial passages made on four samples. In all but 1 of the 12 assays, the ratios of VIA-positive spleen cells to VIA-positive thymus cells were greater than 1 (median, 4.2; range, 0.8–10.7; $P<0.01$, Wilcoxon signed rank test).

DISCUSSION

To our knowledge, this constitutes the first report of successful in vitro infection of lymphocytes with MDV. The evidence that lymphocytes were infected is very strong. 1) Both VIA expression and virus isolation could be demonstrated after more than 40 serial passages of virus in spleen cell suspensions which, because of preparative methods, should have contained few cells other than lymphocytes and macrophages. Macrophage depletion did not reduce the number of susceptible cells. 2) Immunofluorescence methods were used to localize viral antigen in cells that appeared to be lymphocytes on the basis of size and general morphology. 3) Techniques that specifically reduced the number of susceptible cells in a given suspension were those that were designed to eliminate certain subpopulations of lymphocytes.

To serially passage virus, we had to add fresh splenic lymphocyte suspensions at frequent intervals (ideally, every 1–2 days) since cells were not long lived. It was not necessary to match histocompatibility antigens between donor and recipient cells. However, because spleen cells from one genetic strain (UCD-003) appeared less susceptible ($P<0.05$) than those from others (P-2, N-2, S-strain), the question of genetic control over susceptibility to in vitro infection should remain open. Gallatin and Longenecker (*13*) have claimed a genetically controlled difference in prevalence of receptors for the antigenically related turkey herpesvirus on cells from chicken strains differing in susceptibility to MD. In any case, genetic differences important in determining the outcome of in vivo infection, as between resistant N-2 and susceptible P-2 chickens, were clearly not expressed in vitro. This was not surprising since the level of early cytolytic infection in lymphoid organs was shown (*14*) not to correlate with the tumor response, which is the usual criterion for assessing genetic resistance of chicken strains.

The experiments done in attempts to identify the target(s) of in vitro infection gave results mostly in agreement with those we obtained from in vivo infection studies (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication). As in the early phase of in vivo infection, the cells that were found infected after exposure in vitro were among the subpopulations characterized by 1) low or medium density, 2) nylon wool adherence, 3) Fc receptors, 4) surface IgM, and 5) surface Ia-like antigen. The data from our in vivo studies showing that targets of cytolytic infection display Fc receptors and Ia-like antigen could not distinguish between the possibility that these antigens were expressed as a result of herpesvirus infection (*15*) as opposed to the alternate possibility that the susceptible subpopulation was already expressing them. The in vitro experiments reported here prove that the alternate possibility is the true interpretation since removal of cells bearing either antigen significantly decreased the susceptibility of the cell suspension. It is known that B-cells express Ia antigen. However, the question as to whether non-B-lymphocytes express Ia prior to infection remains unresolved.

Carbonyl iron treatment did not remove cells susceptible to cytolytic infection in vitro. In contrast, this treatment caused significant depletion of lymphocytes that were cytolytically infected in vivo. This observation suggests that infection with MDV enhanced depletion of B-cells by carbonyl iron treatment.

The percentage of susceptible cells was higher in the spleen than in the thymus. This observation is not surprising since we (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication) found that VIA-positive cells in the thymus during the cytolytic period of in vivo infection were B-cells, and the proportion of B-cells in the spleen is considerably higher than that in the thymus. Along this line, Gallatin and Longenecker (*13*) found few receptors for turkey herpesvirus on thymus cells.

The bursa also appeared to have a lower number of target cells than the spleen, but caution in interpretation is indicated in that case. While the viability of cultured thymic cells dropped off at the same (or at a slower) rate as that of spleen cells, bursa cells died much more rapidly and this probably affected the assays for infected cells. The results of the trials in which the susceptibility of spleen cells from EBx and intact donors was compared demonstrated the importance of the bursa as a probable origin of target cells. Taken together, the data uniformly support the conclusion that B-cells are the major target for in vitro cytolytic infection. The only suggestion that non-B-cells might also serve as a target for cytolytic infection came from trial 1 (table 5) in which spleen cells from EBx donors had both VIA and virus isolation rates above those expected from inoculum cells alone. Although the percentage of IgM-bearing cells from EBx donors was very low, absolute freedom from B-cells was not established. Thus additional study of this point is warranted.

Little was learned about the target(s) for latent infection. It may be necessary to use DNA hybridization methods to address this very important aspect. The finding of Schat et al. (*16*) that EBx birds exposed to MDV lack cytolytic infections of lymphoid organs but do develop latent infections of splenic and peripheral blood lymphocytes suggests that additional efforts with in vitro infection of cells from EBx donors might be fruitful. Finally, it should be obvious that the methodology reported here might be successfully adapted for studies leading to in vitro transformation. The potential for the use of the in vitro system in the study of the factors that determine the outcome of the virus–lymphocyte encounter is great indeed.

Surface Antigens on Marek's Disease Lymphoblastoid Tumor Cell Lines[1,2,3]

Karel A. Schat,[4] **Chen-Lo H. Chen,**[5] **William R. Shek,**[4] *and* **Bruce W. Calnek**[4,6]

ABSTRACT—A total of 32 Marek's disease virus (MDV)-induced cell lines, 1 avian leukosis virus-induced cell line, and 1 reticuloendotheliosis virus (REV)-induced lymphoblastoid cell line were investigated for the presence of Fc receptors, surface IgM, and Ia-like antigen. Surface IgM and Fc receptors could not be demonstrated on any of the cell lines. Ia-like antigen was detected on all MDV-induced cell lines and on the 1 REV-induced cell line. Ia-like antigen was unrelated to other antigens reported to be present on Marek's disease tumor cells. It was also unimportant as a target antigen for MDV-related, allogeneic cell-mediated cytotoxicity. The densities of the cells of 5 MDV-induced cell lines were established on continuous Percoll gradients. Most cells had densities between 1.05 and 1.06 g/ml.—JNCI 1982; 69:715-720.

It is generally accepted that the thymus-derived lymphocyte (T-cell) is the target cell for transformation by MDV. Evidence for this is mainly that MD lymphoblastoid cell lines are positive for T-cell antigens, when these cells are tested with antisera prepared against thymocytes (*1-4*). Using lactoperoxidase-catalyzed iodination techniques, Ross et al. (*5*), however, were unable to demonstrate the major thymus-specific polypeptide. It was not clear if this inability reflected technical problems or a real absence of this polypeptide. A more definitive description of the subset(s) of lymphocytes transformed by MDV has to await better defined reagents.

Other antigens have been described on transformed cells. The major histocompatibility antigen defined by the *B*-locus and the minor histocompatibility C-antigen are present (*6, 7*). A number of antigens not present on nontransformed lymphocytes can be detected on the surface of tumor cells. Powell et al. (*1*) and later Witter et al. (*8*) described an MATSA, which could be distinguished from the major histocompatibility antigen (*6-8*). In addition, Murthy et al. (*9*) demonstrated the presence of CFA on MD lymphoblastoid cell lines and on an ALV-transformed cell line. More recently, two antigens were shown on cell lines derived from JMV, a nonproducer MD transplant (*10*), but not on other cell lines. Using monoclonal antibodies, Shearman et al. (*11*) described a metastasis-specific antigen, whereas Ikuta et al. (*12*) demonstrated the presence of Forssman antigen. The importance of these antigens for the immune response against tumor cells is not clear. It had been speculated that MATSA was an important antigen for the cell-mediated immune response against tumor cells [reviewed by Calnek (*13*)]. Schat and Murthy (*14*) and Schat et al. (*15*) demonstrated that the in vitro CMC against allogeneic MD tumor cells was not directed against MATSA but against an alloantigen also present on normal spleen cells with the same major histocompatibility complex as the tumor cell.

In other studies on the characterization of MDV-infected lymphocytes (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication), it was shown that the early lytic infection is initiated in vivo in a population of low-density lymphocytes that are positive for Ia, surface IgM, and Fc receptors. Later, other lymphocytes also became infected. Calnek et al. (*16*) corroborated these data by in vitro infection of splenic lymphocytes when they found that deletion of B-lymphocytes significantly reduced the extent of in vitro infection. In this paper, we characterize transformed lymphocytes by showing that they are low-density, Fc receptor-negative and μ-negative, but Ia-positive, cells.

MATERIALS AND METHODS

Experimental chickens and holding conditions.—Two specific-pathogen-free departmental flocks were sources of experimental chickens: P-2 and the highly inbred UCD-003, which are homozygous for the major histocompatibility alleles $B^{19}B^{19}$ and $B^{17}B^{17}$, respectively (*17*). Experimental chickens were held in isolation units.

Lymphoblastoid cells lines.—Thirty-three MD lymphoblastoid cells lines were used for this study. Cell line designations, inducing viruses, and characteristics of the donors of the original tumor are given in table 1. MDCC-CU1 to MDCC-CU43 and LSCC-CU10, an ALV-derived cell line, were developed and reported by Calnek et al. (*4, 18*), MDCC-MSB-1 (*19*) and MDCC-RP1 (*20*) were received from Dr. K. Nazerian (Regional Poultry Research Laboratory, East Lansing, Mich.), and RECC-UT1 (*21*) was from Dr. H. Bose, Jr. (University of Texas, Austin, Tex.).

Virus inoculation.—Passage 11 of the nononcogenic SB-1 strain of MDV was propagated in chicken embryo fibro-

blasts (*22*). For the induction of cytotoxic spleen lymphocytes, 3-week-old UCD-003 chickens received 500 focus-forming units of SB-1 by intra-abdominal injection.

Antisera and complement.—Ascitic fluids from BALB/c mice, inoculated with hybridomas secreting monoclonal antibodies against either the Ia-like (referred to in this paper as Ia) antigen of the chicken or the μ-chain of chicken IgM, were diluted 1:100 and 1:50, respectively, in RPMI-1640 medium. Both monoclonal antibodies were prepared according to the method of Kearney et al. (*23*). Anti-μ was induced by injection of purified IgM and characterized by radioimmunoassay against purified chicken immunoglobulins. This antibody gave staining patterns identical to those seen with highly purified goat anti-chicken μ (*24*) in double-fluorescence staining tests. The detailed characterization of anti-Ia, which is an IgM, will be published elsewhere (Ewert DL, Munchus MS, Chen CH, Cooper MD: Manuscript in preparation).

An alloantiserum against chicken Ia was from Dr. D. Gilmour (New York University, New York, N.Y.). B/L2 was prepared against B^2B^2-linked Ia antigen (*25*) of chickens of lines 6 and 7. Anti-MATSA serum was prepared in rabbits by inoculation with MDCC-MSB-1 cells (*26*). Guinea pig serum was used as a source of complement.

Isopyknic separation of MD lymphoblastoid cell lines.—The density distribution of each of 5 cell lines (MDCC-CU25, 29, 39, 42, and 43) was characterized with the use of a continuous Percoll (Pharmacia Chemicals AB, Uppsala, Sweden) gradient. The preparation of the gradient, the separation of cells, and the determination of the density of the fractions are detailed elsewhere (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication). The density distribution of MD tumor cells was compared to that of normal spleen cells in each test.

Assay for Fc receptors.—Fc receptors on lymphoblastoid cell lines were detected by adherence of the cells to a monolayer of SRBC coated with chicken anti-SRBC serum or NChS (*27*). Twenty-four-well tissue culture plates (Falcon Plastics, Oxnard, Calif.) were used instead of 35-mm tissue culture dishes; otherwise, the conditions were as described elsewhere (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication). Each cell line was tested by the addition of 2.5×10^6 cells/well to two wells with anti-SRBC serum and to two wells with NChS. Normal spleen cells from 4- to 6-week-old chickens were included as a positive control in all tests. Adherence of cells to SRBC coated with NChS was considered as background, and specific adherence was calculated by the following formula: percent specific adherence = percent adherence to SRBC coated with anti-SRBC serum − percent adherence to SRBC coated with NChS.

IFA test.—Ia antigen and surface IgM were detected by IFA tests applied to all cell lines listed in table 1. One to two million cells were resuspended in HBSS-BSA, incubated at room temperature for 30 minutes, centrifuged, and resuspended in 20 μl of monoclonal anti-Ia or anti-μ. After 30 minutes at 4°C, cells were washed once in HBSS-BSA, resuspended in 20 μl of FITC-conjugated goat anti-mouse globulin serum (Cappel Laboratories, Cochranville, Pa.), and kept at 4°C for 30 minutes. Cells were washed once in HBSS-BSA and resuspended in 0.1 ml of HBSS-BSA. Smears of 10 μl were air dried, either fixed with methanol for 4 minutes or left unfixed, rinsed in Tris-buffered saline, and then examined for membrane fluorescence with a Leitz Dialux fluorescence microscope equipped with epi-illumination. Normal splenic lymphocytes were included in each trial to assure that the test could detect cells positive for Ia antigen or μ-chain.

At least 200 cells were scored independently by two investigators for most trials. The presence of Ia was also investigated by staining MDCC-CU20 (B^2B^2), *MDCC-CU31* ($B^{15}B^{15}$), and MDCC-CU36 ($B^{17}B^{17}$) with the B/L2 alloantisera against Ia. The procedure was exactly as above except that FITC-conjugated horse anti-chicken globulin serum (Roboz Surgical Instrument Co., Inc., Washington, D.C.) was used for staining.

Blocking assays.—For the blocking test, 1–2×10^6 cells were incubated with 20 μl of an appropriate "blocking" antiserum for 30 minutes. Cells were then washed in HBSS–BSA and resuspended in 20 μl of the second antiserum. After 30 minutes' incubation, cells were washed once more and then reacted with 20 μl of conjugate as above. The cell lines, antisera, and conjugates used are given in table 4.

Chromium release assays.—Labeling of lymphoblastoid cell lines with 200 μCi of Na^{51}CrO$_4$ (sp act, 200–400 Ci/mg; New England Nuclear Corp., Boston, Mass.) per 10^7 cells was done as previously reported (*28*). Labeled cells were used for AbC lysis and CMC tests.

The AbC lysis test was done as reported before (*14*). Cells were incubated for 30 minutes with monoclonal antibody against Ia and washed. Complement was added. After incubation for 30 minutes at 39°C, the supernatants and the pellets were harvested separately and each was counted for 10 minutes in a Beckman 4000 gamma counter (Beckman Instruments, Inc., Irvine, Calif.). The procedure for the 4-hour CMC test has been reported (*28*). Effector spleen cells were obtained from SB-1-inoculated or control UCD-003 chickens 7 days post inoculation. Effector cells were prepared by established procedures (*14, 28*) with one modification: Cells were separated on a Percoll three-step gradient to concentrate cytotoxic lymphocytes that have a density range of 1.057–1.068 g/ml (Schat KA: Unpublished data). A discontinuous gradient was made with 9.57 and 7.02% Percoll (Pharmacia Chemicals AB). Forty million cells in 11.7% Percoll were carefully placed on the bottom, and the cells were centrifuged for 15 minutes at 400×*g*. Cytotoxic lymphocytes were harvested from the interface formed between 9.57 and 7.02% Percoll. Target cells for the CMC test were reacted with monoclonal antibody against Ia antigen for 30 minutes just before the test or they were left untreated. Target and effector cells were resuspended for AbC and CMC assays in LM-20.

RESULTS

Isopyknic Separation of MD Lymphoblastoid Cell Lines

The results of the two trials are summarized in table 2. Most (78–91%) of the tumor cells were found in fractions 3–5 (density, 1.051–1.060 g/ml), whereas only 9–28% of normal spleen cells were in those same fractions. Small differences in density were observed between P-2-derived tumors and UCD-003-derived tumors; the density of the former was apparently slightly higher than that of the latter, since more of the cells were in the higher fractions. The same differences were observed between normal spleen cells obtained from UCD-003 and P-2 chicks. The densities of the Percoll in all recovered fractions were identical in both experiments.

Fc Receptors

In total, eight tests were done in which the following cell lines were tested for the presence of Fc receptors: MDCC-CU2, 6, 12, 13, 17, 18, 19, 20, 21, 25, 26, 31, 32, 36, 37, 38, 39, 40, 42, and 43, MDCC-RP1, and MDCC-MSB-1. Fc receptor-positive normal spleen cells could be easily demonstrated in all trials with the use of normal spleen lymphocytes (average of percent specific adherence ± SE for eight trials: 26.6±3.3). Normally, 10–40% of the tumor cells adhered nonspecifically to SRBC coated with NChS, depending on the cell line. Specific adherence of cell lines could not be demonstrated; the percentage of specific adherence varied from +8.2 to −12.1%. Four cell lines were also tested after cultivation in a medium without chicken serum to exclude a possible coverage of Fc receptors. Under these conditions we still failed to demonstrate Fc receptors.

Presence of μ and Ia on Lymphoblastoid Cell Lines

IFA test: Normally, 30–40% of the spleen cells were positive for the presence of Ia, and 10–15% of the cells were positive for μ. The intensity of the staining for μ was weak,

TABLE 2.—*Densities of cells of five MD lymphoblastoid lines fractionated on continuous Percoll gradients*

Origin of tumor or spleen cells	Cell line[a]	Passage	Percent cells in fraction indicated[b] (density[c])				
			2 (1.042)	3 (1.051)	4 (1.057)	5 (1.060)	6 (1.063)
UCD-003	Normal spleen (4 wk of age)	—	1.0	3.8	10.0	13.7	15.7

[a] LM-20 was added in lieu of anti-Ia and complement.
[b] C = guinea pig complement.
[c] Mouse monoclonal antibody against chicken Ia.

while the Ia stained intensively. On the one hand, all cell lines, including the avian leukosis cell line LSCC-CU10 and the reticuloendotheliosis line RECC-UT1, were negative for μ. On the other hand, all cell lines were positive for Ia with the exception of MDCC-RP1 and LSCC-CU10. Between 70 and 100% of the cells showed either patchy or complete ring fluorescence. The intensity of the staining was generally quite strong, and cell clumping was occasionally observed. Most cell lines were tested between passage levels 10 and 35. Exceptions were MDCC-CU17, tested at passages 24 and 53; MDCC-MSB-1, tested at passages 116 and 342; and MDCC-RP1, tested at passage 204. There were no detectable differences between low- and high-passage levels of MDCC-MSB-1 and MDCC-CU17 when tested for the presence of Ia.

The alloantiserum against B^2B^2-linked Ia did demonstrate the presence of Ia on MDCC-CU20, a B^2B^2-derived MD cell line, but not on MDCC-CU36 ($B^{17}B^{17}$) or MDCC-CU31 ($B^{15}B^{15}$). Both intensity of staining and number of fluorescing cells were comparable to reactions with monoclonal anti-Ia.

AbC lysis: Eight MD cell lines and RECC-UT1 (table 3) were found to be positive for Ia with the use of an AbC lysis test. The percent release of ^{51}Cr in the presence of anti-Ia and complement varied, but it was always considerably higher than the percent release with LM-20, anti-Ia, or complement. On occasion, the monoclonal anti-Ia seemed slightly toxic for certain cell lines. Interestingly, MDCC-RP1 was positive for Ia in the AbC lysis test but not in the less sensitive IFA test. Ia could not be demonstrated on LSCC-CU10, the ALV-induced cell line.

Blocking Assays

Treatment of MDCC-MSB-1 with antiserum against MATSA did not block the staining of the cells with antiserum against Ia. The reverse was also true. Monoclonal anti-Ia did not block the staining of MDCC-MSB-1 by MATSA (table 4).

Treatment of MDCC-CU20 with monoclonal anti-Ia did prevent the staining of the cells by alloantiserum. However, the alloantiserum did not prevent the recognition of the cells by the monoclonal antibody (table 4), as could be expected for two antibodies detecting a public and a private (allo-) antigenic determinant, respectively.

CMC Assays

In two trials MDCC-CU12 cells were treated either with monoclonal anti-Ia or with LM-20. The coating with anti-

2	None	0	8.09±0.29 (8)	3.87	23.30	2.64	31.78	11.99
	Anti-Ia	42.65	8.83±0.39 (8)	2.63	24.65	2.61	27.95	11.40

[a] Cells were incubated for 30 min in the presence of LM-20 or mouse monoclonal antibody against Ia antigen prior to their use in the CMC assay.
[b] Donors with release of ^{51}Cr outside the $P = 0.001$ confidence limits established for the control group by Student's *t*-test; * = inside the interval.

Ia was effective since the addition of complement resulted in cytolysis (table 5). A total of 10 of 15 SB-1-inoculated chickens yielded cytotoxic spleen cell preparations causing a significant percent specific release. The presence of anti-Ia on the surface of the target cells did not interfere with the percent specific release, nor did it change the percent release in the presence of lymphocytes from control birds.

DISCUSSION

An antigen comparable to the Ia antigen of the mouse and the human being has been detected on chicken B-cells (bursa-derived cells), monocytes, macrophages, and a small population of unidentified mononuclear cells prevalent in the spleen and bone marrow (*29*). The Ia-like antigen of the chicken is closely linked with the B-major histocompatibility complex (*30*). Recently, the Ia antigen has been reported to be present on important subsets of T-cells. Hämmerling et al. (*31*) found that 40% of the T-cells of the mouse carried Ia antigens, but these antigens could be detected only with a fluorescein-activated cell sorter and not by conventional IFA staining or AbC cytotoxicity. These authors calculated that the density of Ia molecules on T-cells was a hundredfold less than that on B-cells. Enhanced expression of Ia on human T-cells has been reported for T-cell leukemias (*32*) and as a result of blast transformation by antigen and mitogen stimulation (*33*).

The presence of Ia-like antigens was clearly demonstrated on all MD cell lines by IFA tests and/or complement lysis. The detection of Ia, as well as the absence of Fc receptors and IgM on the surface of the MD tumor cell lines, is compatible with the suggested T-cell nature of the MD tumor cells. In a recent paper, the question was raised whether Ia-positive T-cells of chickens might be suppressor cells (*25*), as is the case in the mouse (*34*). It would be of considerable interest to search for suppressor factors produced by MD tumor cell lines. The densities of the cell lines examined in this study were comparable to those of the spleen cells that resulted in the establishment of cell lines (Shek WR: Unpublished data).

It is not clear from the data whether MDV-transformed lymphocytes express Ia antigen as a consequence of transformation or whether the expression of the Ia antigen is a prerequisite to infection and transformation. The prerequisite theory would present an attractive explanation for transformation. Following this hypothesis, early infection of B-cells by MDV, as demonstrated elsewhere (Shek WR, Calnek BW, Schat KA, Chen CH: Submitted for publication) and by Calnek et al. (*16*), would induce blast transformation of T-cells, which then would express Ia and become susceptible to infection and neoplastic transformation. Further characterization of subpopulations of lymphocytes susceptible to in vitro infection might answer the question of whether or not Ia is present before infection of T-cells as it is on B-cells.

The finding of Ia on the tumor cells adds one more antigen to the growing list of antigens known to be present on such cells. It is unlikely that this antigen is identical to MATSA, CFA, Forssman antigen, or organ-specific metastasis antigen for the following reasons: 1) Anti-MATSA serum failed to block staining of Ia. 2) CFA was found to be present on LSCC-CU10 (previously named TLT-1) (*9*), whereas we were unable to demonstrate Ia on this cell line. 3) Forssman antigen was found only on JMV-derived cell lines and not on MDCC-MSB-1 (*12*), whereas Ia was present on all MD cell lines. Interestingly, Ia appeared to be present at a lower concentration on the JMV-derived cell line MDCC-RP1 than on the other MD cell lines. 4) A number of the cell lines positive for Ia failed to transplant (*35*), which makes it unlikely that Ia is related to an organ-specific metastasis antigen.

Recently, Schat et al. (*15*) showed that the allogeneic CMC against MD tumor cells was directed against alloantigens. They speculated that this could be against the major histocompatibility B-antigen or the Ia antigen. It now seems unlikely that the CMC was directed against Ia antigen. Coating of Ia with monoclonal antibody covered the public and private major histocompatibility complex-related antigen (blocking assay), but it did not prevent lysis of allogeneic target cells by effector cells.

The one-way blocking of Ia (table 4) by the monoclonal antibody to the reaction with the allo anti-Ia serum suggests that the determinants are situated close to each other; therefore, the large IgM molecules of the monoclonal anti-Ia may have physically blocked the attachment of the alloantiserum.

Some Effects of the Tumor Promoter 12-*O*-Tetradecanoylphorbol 13-Acetate on Cell Interactions In Vitro[1,2]

David E. Maslow,[3] Eric G. Mayhew,[3] *and* Charles E. Wenner[4,5]

ABSTRACT—Studies were made of the effects of the potent tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate (TPA), 4-*O*-methyl TPA (4-*O*-MeTPA), and 4αphorbol 12,13-didecanoate (4αPDD) on the aggregation of embryonic chick cells in gyratory shaker culture, a model system useful for the study of cell adhesion and cell interactions. TPA and, to a lesser extent, 4-*O*-MeTPA significantly reduced the neural retina aggregate size at concentrations as low as 10^{-9} *M* and 10^{-8} *M*, respectively. An inactive isomer, 4αPDD, had no effect up to 10^{-6} *M*. The reduction in aggregate size appeared related to promoter activity since dexamethasone, a steroid that inhibits tumor promotion by TPA, significantly reversed the inhibitory effect of TPA. None of the agents tested affected the sorting pattern in mixed neural retina and heart cultures. The results indicate that intercellular adhesion, as determined by extent of aggregation, is reduced in the presence of TPA. This inhibition is considered to be related to the tumor-promoting activity of TPA.—JNCI 1982; 69: 721–724.

Tumor promoters have been shown to have numerous biological and biochemical effects on normal cells in vitro, frequently resulting in the cells' acquiring characteristics usually associated with the transformed phenotype (*1*). These characteristics include increased plasminogen activator production (*2–4*), decreased fibronectin levels (*5*), stimulation of prostaglandin synthesis (*6*), enhanced cell proliferation (*7*), and altered cell morphology (*7, 8*). This mimicry of transformation is dependent on the continued presence of the promoters, without which the cells revert to their original phenotype (*9*), and such changes have not been uniformly observed in all cells studied.

There is much evidence to suggest that the cell membrane may be the major site of action of TPA, an extremely potent and widely used tumor promoter (*10–12*). TPA has also been shown to be a highly potent inhibitor of terminal differentiation in many cell systems (*9, 13–16*), although in some cases it has been shown to induce rather than inhibit differentiation (*17, 18*). TPA may also act to induce permanent phenotypic changes (*19, 20*).

The aggregation of embryonic cells in gyratory shaker culture is a model system for the study of cell interactions in which the size of the aggregates, the differentiation of the cells, and the sorting of the cell types are reproducible standards of normal cell behavior, which can act as sensors of the effects of added agents (*21*). Because of the effects of tumor promoters on cells and their surfaces, it was of interest to determine what effect TPA might have on this aspect of normal cell behavior.

MATERIALS AND METHODS

Neural retina cells were isolated from 10- to 11-day chick embryos with crystallized trypsin (Enzar-T; Armour Pharmaceutical Co., Phoenix, Ariz.) following the optimal procedure described by Barnard et al. (*22*). We isolated heart cells from 9-day-old embryos by repeatedly pipetting trypsinized, minced heart fragments. Viability determinations with trypan blue indicated that the viability of treated neural retina cells remained better than 90% up to 24 hours after treatment.

Aggregation was furthered by culture of 6×10^6 neural retina cells alone or together with 1×10^5 heart cells in 3 ml of Eagle's minimum essential medium with 10% horse serum in a 25-ml Erlenmeyer flask on a gyratory, incubator shaker rotating at 70 rpm. After 24 hours in culture the diameters of 50 neural retina aggregates from each treatment group were measured with an eyepiece micrometer (Carl Zeiss, Ober Kochen, Federal Republic of Germany). Mixed aggregates were fixed in Gendre's fixative after 72 hours in culture for periodic acid–Schiff staining to distinguish the glycogen-rich heart cells.

TPA and 4-*O*-MeTPA were obtained from Chemical Carcinogens (Eden Prairie, Minn.) dexamethasone from Sigma Chemical Co. (St. Louis, Mo.), and 4αPDD from Lifesystems Co. (Newton, Mass.). Stock solutions at 10^{-3} *M* in ethanol were diluted in culture as indicated; control cultures received ethanol equivalent to the highest dose.

Changes in diameter measurements do not accurately reflect the true extent of the differences in aggregate volume and number of cells contained. (A 20% reduction in diameter, for example, indicates a reduction in volume of ≈49%.) However, we present the data for mean diameters that were actually measured, rather than for mean volumes, which may be calculated from those measurements.

RESULTS

Table 1 gives the mean diameter of aggregates formed in neural retina cultures containing tenfold dilutions of the potent tumor promoter TPA and of an isomer with reduced activity, 4-*O*-MeTPA. A significant reduction (Student's *t*-test, $P<0.01$) in aggregate size was obtained with TPA at concentrations as low as 10^{-9} *M* and with 4-*O*-MeTPA at concentrations as low as 10^{-8} *M*. At 10^{-6} *M* and 10^{-7} *M*,

TABLE 1.—*Effect of TPA and its analogs on aggregation of neural retina cells*[a]

Concentration, M	Control		TPA	4-*O*-MeTPA	4αPDD
	−Solvent	+Ethanol, 0.01%			
0	248.9±5.2 (250)	240.1±3.9 (250)			
10^{-9}			230.9±3.5 (150)	236.2±4.0 (150)	
10^{-8}			219.7±2.7 (250)	226.2±3.6 (250)	258.7±5.4 (100)
10^{-7}			208.6±3.4 (200)	221.6±3.1 (200)	249.2±4.4 (100)
10^{-6}			198.9±2.9 (250)	218.8±4.0 (250)	242.2±3.8 (100)

[a] 6×10^6 neural retinal cells were maintained in gyratory shaker culture under conditions favoring aggregation with TPA or its analogues at concentrations up to 10^{-6} *M*. After 24 hr of culture, at least 50 aggregates from each group were measured with an eyepiece micrometer. Numbers are aggregate sizes (μm) ± SE (No. measured). Statistical significance based on Student's *t*-test is given in text.

TABLE 2.—*Effect of dexamethasone on inhibition of neural retina cell aggregation by TPA*[a]

Experimental series	Dexamethasone concentration, M	Control		−TPA	+TPA 10^{-7} M	+TPA 10^{-6} M
		−Solvent	+Ethanol, 0.01%			
1	0	227.9±7.3	192.8±7.0		160.1±5.1	
	10^{-8}			222.9±7.2	197.4±6.4	
	10^{-7}			224.8±6.6	193.8±6.0	
	10^{-6}			202.1±6.2	195.3±4.2	
2	0	231.6±4.4	213.6±3.8		204.1±3.1	193.3±2.2
	10^{-7}			219.9±3.4	232.5±3.8	213.6±3.1

[a] 6×10^6 neutral retina cells were maintained in gyratory shaker culture under conditions favoring aggregation with either TPA or TPA and dexamethasone. After 24 hr of culture, at least 50 aggregates from each group were measured with an eyepiece micrometer. Numbers are aggregate sizes (μm) ± SE; 250 aggregates are measured in expt 1 and 200 in expt 2. Statistical significance based on Student's *t*-test is given in text.

TPA was significantly (P<0.01) more inhibitory than 4-*O*-MeTPA; the differences in aggregate size at 10^{-8} *M* (0.1>P>0.3) were not significant. We also treated cultures with 4αPDD, an isomer with no reported promoter activity, to determine if the observed inhibition with TPA and 4-*O*-MeTPA was due to the promoter-related activity of the phorbol esters added, and the results are also shown in table 1. Aggregate diameters were not reduced at any of the concentrations of 4αPDD tested.

To further demonstrate that the reduction in aggregate size in cultures containing TPA or 4-*O*-MeTPA was not unrelated to their promoter activities, we added dexamethasone to aggregating cultures containing TPA at 10^{-6} *M* or 10^{-7} *M*. Dexamethasone is a steroid that inhibits tumor promotion by TPA (*23*). A reversal by the dexamethasone of the inhibitory action of TPA on cell aggregation would indicate that the dexamethasone is blocking one or more of the events associated with and likely required as part of the promotion process. No effect by the dexamethasone on the TPA-related inhibition of cell aggregation would suggest that its antipromoter effect is on some other aspect of the promotion process but would not rule out the inhibition as a required part of tumor promotion. The results of these experiments are summarized in table 2. The differences in the sizes of similarly treated aggregates between the former experimental group and these are within the normal range experienced with neural retina aggregates and may be due to seasonal differences in eggs or different serum lots. The addition of dexamethasone alone at these doses tested caused no decrease in aggregate size. However, dexamethasone when added to aggregating cultures containing TPA at both 10^{-6} *M* and 10^{-7} *M* caused a significant (P<0.001) reversal of inhibition of the TPA, although the aggregates were still smaller than those treated with dexamethasone alone at the same concentration.

We also added TPA to aggregating cultures of neural retina and heart cells and examined the sorting pattern and extent of differentiation in periodic acid–Schiff-stained aggregate sections. There was no effect of TPA up to a concentration of 10^{-6} *M* on the normal sorting pattern of a central heart area surrounded by peripheral neural retina cells compared to the pattern seen in control cultures. In addition, the frequency and appearance of retinal rosettes characteristic of neural retina aggregates did not differ in control and treated cultures. However, the aggregates formed in treated cultures were significantly smaller (0.01>P>0.001) than those in the control cultures.

DISCUSSION

Embryonic fibroblasts have been utilized in experiments analyzing the in vitro biological effects of tumor promoters, including their adhesion and orientation on artificial substrata (*24*), but they were usually secondary cultures and the properties studied were not related to their differentiation. The effect of TPA on the differentiation of normal cells in primary cultures has been uniformly inhibitory in contrast to less consistent results with transformed cells (*9*). The sizes of aggregates formed in cultures of primary embryonic cells can be similarly considered in vitro characteristics of differentiation related to in vivo behavior (*25*) and can serve to monitor changes in cell–cell adhesion. Aggregate size has been used by many investigators to study changes at the cell surface and effects of exogenous agents on cell interactions. Treatment with trypsin (*26*), protein synthesis inhibitors (*27*), cytoskeletal disrupters (*28, 29*), and other surface active agents (30, 31) has been shown to cause changes in the aggregation behavior of the cells. The size of aggregates also has been used to study the effect of the presence of metal cations (32) and various anticancer agents (33) on cell behavior. In addition, the differential inhibition of neural retina aggregates is an assay procedure useful for demonstrating the presence of small numbers of cancer cells (34, 35). Thus the aggregation of embryonic cells should be a useful additional in vitro tool for the study of the biological effects of tumor promoters, and the extent of inhibition observed in these experiments (20% of aggregate diameter or 49% of aggregate volume) is within the ranges reported for other studies using aggregate size as a sensor of changes in cell interactions.

Our results indicate that the presence of active tumor promoters such as TPA and, to a lesser extent, 4-*O*-MeTPA results in the formation of aggregates of reduced size, reflecting possible promoter-induced changes in the extracellular adhesion of these freshly isolated cells, whereas the nonactive isomer 4αPDD had no inhibitory effect. These results indicate that the reduction of aggregation caused by the active tumor promoters correlates with their promoter activity. The mechanisms of action of the two related compounds may differ, however, possibly related to the correlation between the presence of TPA and the induction of prostaglandin synthesis (6), hyperplasia, or other changes not found with 4-*O*-MeTPA (36) and not simply from nonspecific hindrance of adhesion caused by adsorption of the relatively small molecules to the surface of the cells. It still remains to be resolved whether these changes are obligatory or dissociable events following TPA exposure (37, 38). First-stage promoter activity has been reported for 4-*O*-MeTPA (39, 40) in contrast to the full promoter capabilities of TPA, which may also account for the smaller effect of 4-*O*-MeTPA.

The results from the experiments in which the presence of dexamethasone, a steroid shown to be highly effective in inhibiting tumor promotion by TPA (23), was correlated with a reversal of the inhibitory action of TPA suggest a causal relationship between the tumor-promoting activity of the TPA and reduced cell–cell adhesion. The mechanism of this inhibition of tumor promotion is unknown, although dexamethasone and other steroid anti-inflammatory agents act to reduce plasminogen activator and prostaglandin activity in treated cells (41, 42). Dexamethasone also inhibits the binding of TPA in vivo, but not by competitively binding to the same sites (43, 44). The lack of effect of TPA up to a concentration of 10^{-6} *M* on the normal sorting pattern of neural retina and heart cells indicates that the effect of tumor promoters on cell behavior in our experiments is to reduce nonspecific cell adhesion without affecting specific cell interactions. The sorted configuration formed in mixed aggregation cultures has been shown to be remarkably resistant to disruption by exogenous agents with the sole exception of cytochalasin B (28, 29).

There have been reports of both the enhancing (45, 46) and inhibitory (20, 47) effects of tumor promoters on cell–substrate adhesion, but we report here on their effects on cell–cell adhesion. Since the difference in the mechanisms of these two adhesive processes themselves are not yet clearly understood, it is premature to extrapolate from the effects of tumor promoters in one case to the other. However, the many changes in cells and cell surfaces caused by TPA suggest several possibilities. Reduced aggregation as a result of increased electrostatic repulsive forces is unlikely in view of the results of Wenner et al, (11) showing that TPA at 10^{-6} *M* caused a reduction in the electrophoretic mobility of mouse Ehrlich ascites cells, reflecting a reduced net negative surface charge density. TPA also disrupts actin filaments normally present at the cell periphery (48), as well as other cytoskeletal elements, which may be reflected in reduced adhesive capabilities. This observation of perturbed cytoskeletal integrity may also support the possible role of alterations in intracellular calcium ion movement in response to tumor promotion suggested by the work of Boynton and Whitfield (49) and is consistent with our preliminary observation of significant reductions in the size of aggregates formed in cultures containing calcium ionophore A23157 at concentrations of 1 μg/ml ($0.5>P>0.02$) and 2, 5, or 10 μg/ml ($P<0.001$). Also, tumor promoters cause a marked increase in plasminogen activator synthesis. The proteases produced may act to reduce the strength of adhesion of the cells, thereby enhancing their likelihood of separation by the shearing forces present in gyratory shaker culture. Tumor-promoting but not nonpromoting phorbol esters also produced a relatively specific decrease in the synthesis of some glycoproteins and other glycoconjugates correlated with the induction of anchorage independence; both were reversible by retinoic acid, a potent inhibitor of TPA tumor promotion (50). These observations are consistent with the reductions in intercellular matrix and fibronectin synthesis that have been reported (5, 51). Finally, any of the other reported effects of tumor promoters on cells may affect the adhesion and aggregation of the cells in a direct way or in ways not yet apparent to produce the reduction in intercellular adhesion, as measured by aggregate size, reported here.

Mouse Skin Tumor-Initiating Activity of 5-, 7-, and 12-Methyl- and Fluorine-Substituted Benz[*a*]anthracenes[1,2,3]

Alexander W. Wood,[4] Wayne Levin,[4] Richard L. Chang,[4] Allan H. Conney,[4] Thomas J. Slaga,[5] Robert F. O'Malley,[6] Melvin S. Newman,[7] Donald R. Buhler,[8,9] *and* Donald M. Jerina[8]

ABSTRACT—As an approach for elucidation of structure activity relationships that underlie the exceptionally large difference in carcinogenic activity between benz[*a*]anthracene and 7,12-dimethylbenz[*a*]anthracene (7,12-DMBA), 11 methyl- and/or fluorine-substituted benz[*a*]anthracenes were evaluated for tumor-initiating activity on mouse skin. Outbred CD-1 and outbred Sencar mice received a single topical application of the hydrocarbons followed by twice weekly applications of the tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate for 16–26 weeks. 7,12-DMBA was almost two orders of magnitude more active as a tumor-initiator than 7- and 12-methylbenz[*a*]anthracene. Methyl substitution at the 7- and 7,12-positions of benz[*a*]anthracene was significantly more effective in the enhancement of tumorigenic activity than fluorine substitution at these positions. Although 7-fluorobenz[*a*]anthracene, 12-fluorobenz[*a*]anthracene, and 7,12-difluorobenz[*a*]anthracene had only 0.15, 0.26, and less than 0.005 times the tumor-initiating activity of their respective methyl-substituted derivatives, they were severalfold more active than benz[*a*]anthracene. 7-Fluorobenz[*a*]anthracene was slightly less active than 12-fluorobenz[*a*]anthracene, whereas 7-methylbenz[*a*]anthracene was about twofold more active than 12-methylbenz[*a*]anthracene. For 7,12-disubstituted benz[*a*]anthracenes, 7-methyl-12-fluorobenz[*a*]anthracene was more than twice as tumorigenic as 7-fluoro-12-methylbenz[*a*]anthracene, but each was individually more active than 7-methylbenz[*a*]anthracene and 12-methylbenz[*a*]anthracene, respectively. Both fluorinated compounds were much less active than 7,12-DMBA. Substitution of fluorine or methyl at the 5-position of 7-methylbenz[*a*]anthracene and substitution of fluorine at the 5-position of 12-methylbenz[*a*]anthracene dramatically reduced their tumorigenic activity.—JNCI 1982; 69:725–728.

The polycyclic aromatic hydrocarbons represent a particularly intriguing class of environmental carcinogens in that seemingly small changes in structure can have profound effects on biologic activity. A striking example of this phenomenon is seen from a comparison of the structure and carcinogenicity of BA and 7,12-DMBA (text-fig. 1). Whereas BA is at best a weak carcinogen and has been described as noncarcinogenic in several tumor models, 7,12-DMBA is an extremely potent carcinogen in a variety of tumor models and is the most potent of the polycyclic hydrocarbons with respect to tumor-initiating activity on mouse skin (*1*). This striking difference in biologic activity is made all the more intriguing by the fact that a significant amount of experimental (*2–17*) as well as theoretical (*18, 19*) evidence indicates that a 3,4-diol-1,2-epoxide in which the 1,2-epoxide forms part of a bay region in the metabolite is an ultimate carcinogen of both BA and 7,12-DMBA. At present, an adequate physicochemical or biochemical basis by which the large difference in biologic activity of these two hydrocarbons can be explained is unavailable. In an attempt to elucidate the structure–activity relationships that underlie the exceptionally large difference in carcinogenic activity between BA and 7,12-DMBA, we have synthesized and tested the skin tumor-initiating activity of 11 methyl- and/or fluorine-substituted derivatives of BA.

MATERIALS AND METHODS

Chemicals.—TPA was obtained from Dr. Peter Borchert, Chemical Carcinogenesis, Inc., Eden Prairee, Minn. Organic solvents were obtained from Fisher Scientific Co., Springfield, N.J., and Burdick & Jackson, Inc., Muskegon, Mich.

BA derivatives.—A sample of BA obtained from Eastman Kodak Co., Rochester, N.Y., was judged to be pure by HPLC (*17*) and was used as such. Both 7-MBA (*20*) and 12-MBA (*21*) were synthesized as previously described. 7,12-DMBA, obtained from Aldrich Chemical Co., Milwaukee, Wis., was purified by column chromatography on silica gel eluted with cyclohexane and stored in the dark before use. 5,7-DMBA was prepared as described in (*22*). 7-FBA, 12-FBA, and 7,12-DFBA were prepared by anodic fluorination of BA (*23*). Both 5-F-7-MBA (*24*) and 5-F-12-MBA (*25*)

ABBREVIATIONS USED: BA=benz[*a*]anthracene; 7,12-DFBA=7,12-difluorobenz[*a*]anthracene; 3,4-diol-1,2-epoxide=either or both diastereomerically related 3,4-dihydroxy-1,2-epoxy-1,2,3,4-tetrahydrobenz[*a*]anthracenes in which the benzylic 4-hydroxyl group and the bay-region 1,2-epoxide oxygen are either *cis* or *trans*; DMBA=dimethylbenz[*a*]anthracene; FBA=fluorobenz[*a*]anthracene; 7-M-12-FBA-7-methyl-12-FBA; HPLC-high pressure liquid chromatography; MBA=methylbenz[*a*]anthracene; 5-F-7-MBA=5-fluoro-7-MBA; 5-F-12-MBA=5-fluoro-12-MBA; 7-F-12-MBA=7-fluoro-12-MBA; TPA=12-*O*-tetradecanoylphorbol 13-acetate.

BENZ [a] ANTHRACENE (BA)

7,12-DIMETHYLBENZ [a]-ANTHRACENE (7,12-DMBA)

TEXT-FIGURE 1.—Structure of BA and 7,12-DMBA.

were obtained from fluorinated naphthalene, whereas 7-F-12-MBA and 7-M-12-FBA were synthesized (*26*) from BA-7,12-dione. All synthetic compounds were judged to be of analytic purity on the basis of microanalytic combustion data as indicated in the above references (*20–26*). Furthermore, the products obtained by anodic fluorination were free of cross-contamination as judged by HPLC.

Tumorigenicity studies.—Outbred CD-1 mice were obtained at 6 weeks of age from Charles River Breeding Laboratories, Wilmington, Mass. Outbred Sencar mice, originally obtained from Dr. R. K. Boutwell, University of Wisconsin, Madison, Wis., are presently raised at Oak Ridge National Laboratory. Only female mice were used for tumor experiments. At approximately 8 weeks of age, the dorsal surfaces of the mice were shaved with electric clippers. Two to 4 days later, mice in the resting phase of their hair cycle received a single topical application of the test compounds in 200 μl acetone. Control animals received solvent only. Each treatment group was comprised of 30 mice housed at 15 animals/cage.

The tumor promoter TPA was applied in 200 μl acetone twice weekly to each mouse, commencing 7 days after administration of the test compounds. CD-1 mice received 16 nmol TPA/application, whereas Sencar mice received 3.2 nmol/application. Incidence of papillomas was recorded once every 2 weeks. For purposes of comparison, the significance of relative tumorigenic activity was evaluated by Student's *t*-test.

RESULTS

The skin tumor-initiating activities of BA and six methyl- or fluorine-substituted derivatives at the 7- and/or 12-positions of BA in CD-1 mice after 18 and 26 weeks of tumor promotion with TPA are summarized in table 1. In agreement with numerous other studies, BA was a weak tumor initiator. A 500-nmol dose of the hydrocarbon did not significantly increase the tumor incidence above solvent control levels, whereas a 2,500-nmol dose induced tumors in 38% of the mice with an average of 0.67 papillomas/mouse at 26 weeks of promotion. In contrast, a single 10-nmol dose of 7,12-DMBA induced 3.6 tumors/mouse at 18 weeks of promotion and was thus over three orders of magnitude more active than BA. Comparison of papillomas/mouse at 26 weeks of promotion indicated that 7-FBA and 12-FBA were 4–11 times more tumorigenic than BA. 7,12-DFBA was more active than BA, but the lack of comparable doses or information on the shape of the dose-response curves makes precise comparisons difficult. All three of these fluoro-substituted BA derivatives, however, were less active than the corresponding methyl-substituted BA derivatives. Thus at 26 weeks of promotion a dose of 100 nmol of 7-MBA was six times more tumorigenic than 7-FBA, and 12-MBA was almost four times more active than 12-FBA. At 18 weeks of promotion 7,12-DMBA was at least 100 times more active than 7,12-DFBA. Whereas a 100-nmol dose of 7-MBA was not significantly more active than the same dose of 12-MBA at 26 weeks of promotion (0.87 vs. 0.67 tumors/mouse, $P>0.5$), 7-MBA was up to 4.6 times more tumorigenic than 12-MBA when higher doses were compared at 18 weeks of promotion. 7-MBA showed a linear dose response with respect to average numbers of papillomas/mouse over a tenfold dosage range, whereas tumor incidence with 12-MBA did not increase proportionately over the same dosage range. This nonproportionality in the dose-response curve of 12-MBA also explained the diminished difference in tumorigenic activity between 12-FBA and 12-MBA when higher doses of the two compounds were used.

Table 2 summarizes the skin tumor-initiating activity of eight BA derivatives in Sencar mice after 16 weeks of tumor promotion with TPA. Sencar mice were developed by inbreeding mice that had a high susceptibility to DMBA-initiated skin tumors. DiGiovanni et al. (*27*) have shown that higher tumor incidences are observed at an earlier time and with lower doses of TPA in Sencar mice compared to those in CD-1 mice. Consistent with observations in CD-1 mice (table 1), 7-MBA was about twofold more tumorigenic than 12-MBA in Sencar mice, and 7,12-DMBA was about 80 times more tumorigenic than 7-MBA. The high tumori-

TABLE 1.—*Comparison of the effects of methyl and fluorine substitution at the 7- and 12-positions on the skin tumor-initiating activity of BA in CD-1 mice*[a]

[a] Thirty female CD-1 mice received a single topical application of compound in 200 μl acetone; 7 days later the mice received twice-weekly topical applications of TPA (16 nmol/application) in 200 μl acetone. In each group 27–30 mice were alive at the end of 26 wk of tumor promotion. ND=not determined.

[b] Values are means ± SEM.

TABLE 2.—*Comparison of the effects of methyl and fluorine substitution on the skin tumor-initiating activity of 7-methyl-BA and 12-methyl-BA in Sencar mice*[a]

Compound	BA dose, nmol	Percent of mice with papillomas	Papillomas/mouse[b]
Solvent	0	0	0
7-MBA	400	86	3.00±0.52
12-MBA	400	73	1.65±0.28
7,12-DMBA	10	100	6.43±0.53
	400	100[c]	22.62±1.93[c]
7-M-12-FBA	400	100	9.00±0.94
7-F-12-MBA	400	88	3.43±0.38
5-F-7-MBA	400	33	0.44±0.08
5,7-DMBA	400	41	0.63±0.12
5-F-12-MBA	400	10	0.21±0.05

[a] Thirty female Sencar mice received a single topical application of compound in 200 μl acetone; 7 days later the mice received twice-weekly topical applications of TPA (3.2 nmol/application) in 200 μl acetone. In each group 28–30 mice were alive at the end of 16 wk of tumor promotion.

[b] Values are means ± SEM.

[c] Results were calculated at 10 wk of tumor promotion with TPA.

genicity of 7-MBA was markedly decreased by introduction of either a fluorine or a methyl group at the 5-position of 7-MBA. Similarly, the average number of papillomas/mouse with 12-MBA was reduced from 1.6 to 0.20 as the result of substitution by fluorine at the 5-position. Substitution of fluorine at position 12 of 7-MBA and at position 7 of 12-MBA significantly increased the tumorigenicity of the hydrocarbons. Thus 7-M-12-FBA was three times more active as a tumor initiator than 7-MBA (9 vs. 3 papillomas/mouse), and it was the second most active compound tested. 7-F-12-MBA was two times more active as a tumor initiator than 12-MBA (3.4 vs. 1.6 papillomas/mouse).

DISCUSSION

Although other pathways of activation may occur, studies of the mutagenicity, metabolism, tumorigenicity, and DNA binding of BA, 7-MBA, and 7,12-DMBA and their metabolites have indicated that metabolic formation of bay-region diol epoxides is the principal pathway by which these hydrocarbons are activated to ultimate carcinogens (*2–19*). Consistent with earlier reports [cf. (*1*)], the present study has found that 12-MBA is tenfold to twentyfold more active, 7-MBA is about fiftyfold more active, and 7,12-DMBA is greater than one thousandfold more active than BA as a tumor initiator. Some of the factors that could be responsible for these dramatic differences in activity consist of the steric and electronic effects of substituents in altering 1) the rate and extent to which these hydrocarbons are metabolized to reactive metabolites, 2) the effectiveness with which these metabolites bind to critical cellular nucleophiles, and 3) the rate at which such damage is repaired. In general, the electronic effect of a methyl substituent on an aromatic ring is one of activation via hyperconjugation, whereas a fluorine substituent deactivates via induction but still acts as an ortho–para director via resonance. Thus direct electronic interaction (resonance stabilization) of a C-1 carbocation derived from a bay region 3,4-diol-1,2-epoxide in the BA series can be expected for C-7 but not C-12 substituents. Since fluorine is only slightly larger than hydrogen, they should exert similar steric effects. However, a 12-methyl substituent is known to cause nonplanarity in 12-MBA and 7,12-DMBA due to adverse steric interaction with the C-1 hydrogen across the bay region. Little is presently known about the positional reactivity of nonplanar aromatic hydrocarbons compared to their planar analogues.

The fiftyfold-higher tumorigenicity of 7-MBA relative to BA is higher than might be expected on the basis solely of enhanced reactivity of the bay region diol epoxide due to the 7-methyl substituent. Some of the difference in activity may be due to the metabolism profiles suggesting that the 3,4-dihydrodiol, the immediate metabolic precursor of the bay region 3,4-diol-1,2-epoxide, is a more prominent metabolite of 7-MBA than of BA (*17, 28*). Although 7-substitution has been proposed to block a principal route of metabolic detoxification of BA, there is apparently little if any metabolism of BA at the 7-position (*17*). Comparative studies on the metabolic conversion of the 3,4-dihydrodiol of BA and 7-MBA to their respective 3,4-diol-1,2-epoxides have not been reported. However, studies with BA 3,4-dihydrodiol indicate that it is not efficiently converted to its bay region diol epoxide (*7*). Since 12-MBA is tenfold to twentyfold more active than BA, presumably due to some type of steric effect, the cumulative influence of 7- and 12-methyl substituents might account for the one thousandfold-greater activity of 7,12-DMBA over the activity of BA.

The above arguments are, however, fragile when considered in light of the tumorigenicity of the fluorinated BA's in the present study. Although fluorine at the 7-position of BA could slightly decrease the reactivity of its bay-region diol epoxide, 7-FBA is greater than threefold-more active than BA. Although a fluorine at position 12 has little steric effect relative to hydrogen, 12-FBA is greater than sevenfold-more active than BA. The cumulative effect is small since 7,12-DFBA, although more active than BA, has only 1% of the activity of 7,12-DMBA. Replacement of either methyl group by fluorine in 7,12-DMBA results in an approximately fiftyfold loss in activity, yet 7-M-12-FBA and 7-F-12-MBA are twofold- to threefold-more active than 7- and 12-MBA, respectively. Thus fluorine substitution at the 7- and/or 12-positions enhances tumorigenic activity relative to the unfluorinated compound but not as much as methyl substitution. Although the present results have not provided a basis by which substitution at the 12-position enhances the tumorigenicity of BA, they do emphasize the importance of either a methyl or a fluorine substituent in enhancing tumorigenicity when the substituent is in the bay region but not on the critical benzo-ring. This is also the case for 5-methylchrysene (*1, 29, 30*) and 11-methylbenzo[*a*]pyrene (*31*).

When formulating the bay region theory (*19*), we noted that substituents peri to the critical benzo-ring (the 5-position in BA) often decrease tumorigenic activity. This effect seems to be generally true for the BA series since 5-F-7-MBA and 5,7-DMBA have less than 20% of the activity of 7-MBA, 5-F-12-MBA has less than 15% of the activity of 12-MBA (table 2), and 5-fluro-7,12-DMBA has less than 1% of the tumor initiating activity of 7,12-DMBA (*32*). Similarly, substitution of fluorine at the 12-position (peri to the critical benzo-ring) of 5-methylchrysene markedly inhibits tumorigenic activity (*29, 30*). Although the basis of this "peri effect" is presently unknown, it is possible that certain substituents cause dihydrodiols with bay region double bonds to adopt a quasi-diaxial conformation. For some but not all dihydrodiols, this conformation results in poor conversion to bay region diol epoxides (*33–38*).

Free Amino Acid Pools of Rodent Mammary Tumors[1, 2, 3]

Martin J. Pine,[4] Untae Kim,[5] *and* Clement Ip[6, 7]

ABSTRACT—Intracellular pools of free amino acids were compared individually in mammary tumors of Wistar Furth and Sprague-Dawley rats and C3H and DBA/2 mice. Of 11 transplantable and 7,12-dimethylbenz[*a*]anthracene-induced adenocarcinomas of the rat, all nonmetastasizing tumors could be distinguished from metastasizing tumors by the accumulation of high glutamine pools and significant-to-high cystathionine pools. In primary mammary tumors of C3H mice and transplanted mammary tumors of DBA/2 mice, intracellular free arginine was frequently below that of the circulating plasma level and approached that in the arginine-destroying organ, the liver. Arginine pool depletion was also noted in normal mammary tissue, particularly in the actively lactating mouse. Individual rat or mouse mammary tumors also contained high levels of taurine, β-alanine, and γ-aminobutyric acid, which, like cystathionine, are distinctive for or are enriched in neural tissue. None of these pool enrichments were characteristic of normal rat or mouse mammary tissue. Free hydroxyproline was low in primary induced rat mammary tumors and higher in transplanted mammary tumors and in normal lactating mammary glands, particularly in the mouse. In contrast, the hydroxyproline residues of collagen, taken as an index of mesenchymal cell contribution, were very low in all tumors.—JNCI 1982; 69:729–735.

Free amino acid pools have been examined in several human and animal tumor systems. Alterations in plasma aminogram profiles have been noted in patients with leukemia (*1*), carcinoid syndrome (*2*), or malignant bone tumors (*3*). The relatively indirect cachectic effects of tumor growth on the aminogram profile of host plasma has also been studied in tumor systems of human beings (*4*) and rats (*5*). The plasma aminogram alterations found in those studies were variously attributed to characteristic properties of the tumor to adjustments in host amino acid metabolism and to the increased turnover of collagen. In minimal deviation rat hepatomas, the amino acid pools of host and tumor tissue have also been examined as potential sites of depletion by the surviving amino acid-metabolizing enzymes of the tumor (*6*). Neuroblastomas, gliomas, and other brain tumors have been compared to their metastases for retention of the distinctive profiles of taurine, cystathionine, GABA, and other amino acids found in the neural tissue (*7, 8*).

We were initially interested in the aminogram profiles of established rat mammary adenocarcinomas (*9*) for their possible relevance to variations of tumor growth rate and metastatic potential. Our findings with these and additional rodent mammary tumors show that a tumor type in a given species can exhibit distinctive patterns of free amino acid pool content, and that these may be useful in tumor prognosis and in the design of tumor antagonists.

MATERIALS AND METHODS

Tumor systems.—Transplanted rat mammary tumor lines were carried by subcutaneous implantation in WF female rats. Each line has maintained differentiation and metastatic potential as previously described (*9*). Primary rat mammary tumors were induced by gastric intubation of 10 mg DMBA in 1 ml corn oil in 50-day-old female SD rats. The animals were fed a semisynthetic diet with 20% casein content (*10*). Tumors were harvested at intervals up to 6 months after induction. All tumors except the smallest one were examined histologically and confirmed as well-differentiated, nonmetastasizing adenocarcinomas. The SMT-F and SMT-S nonmetastasizing tumors were maintained subcutaneously in DBA/2HaDD mice grown in the West Seneca Laboratories, West Seneca, N.Y., and fed Teklad (4% fat) diet. Spontaneous mammary tumors, all histologically confirmed as moderately- to well-differentiated nonmetastasizing adenocarcinomas, were from retired C3H/St female breeders grown in the West Seneca Laboratories. The animals were anesthetized, and mice were bled from the ocular plexus and rats from the aorta, with the use of heparinized instruments. Blood was centrifuged and the plasma was inactivated within 5 minutes after bleeding, with 4 volumes of 5% sulfosalicylic acid. For milk collection, about 0.1 ml of milk was aspirated from the two posterior gland pairs of an actively nursing (BALB/c♀ × DBA/2HaDD♂)F_1 mouse that had been anesthetized with Nembutal and received an ip injection of 0.4 U of oxytocin (Parke-Davis, Morris Plains, N.J.). Tumor samples were rapidly excised at their underside and freed of necrotic tissue and capsule. Cystlike or necrotic areas, which were common only in spontaneous C3H mouse tumors, were very briefly scraped and rinsed away in phosphate-buffered saline and blotted dry. Samples were weighed and ground within 1 minute of removal with 4 volumes of 5% sulfosalicylic acid in a conical glass tissue homogenizer. The rat tumor extracts usually required high-speed centrifugation for removal of lipid particles. The deproteinized extracts of tumor and plasma were neutralized with lithium citrate buffer and LiOH to bring them to pH 2.28. For hydrolysate analysis, tumor protein was purified by being boiled in 0.5 *N* $HClO_4$ for 30 minutes and then

washed in 0.1 *N* $HClO_4$, acetone, and $CHCl_3$–CH_3OH at 1:2 dilution. The protein was hydrolyzed in 5 *N* HCl for 28 hours at 100°C without evacuation. Soluble calf skin collagen was also hydrolyzed and assayed for hydroxyproline as a pure collagen standard. Amino acid assays were performed with the Beckman 121M amino acid analyzer, with the use of a one-column Li^+-based physiologic program (*12*). Abbreviated programs were used to assay hydroxyproline, GABA, and arginine; also, for arginine a short column was used. To confirm the identity of GABA, the physiologic program was abbreviated to begin with the third buffer, which removed a small interfering peak. The identity of cystathionine was substantiated by its disappearance upon performic acid oxidation. A solution of 50% H_2O_2–formic acid, 1:5 dilution, was developed for 30 minutes at room temperature, and 8–20 µl were added to 200 µl of the sample. The sample was then reneutralized. This procedure did not appreciably destroy 3,4-dihydroxyphenylalanine, which comigrates with cystathionine. Amino acids were also identified from their 440- to 570-nm peak area ratios and from their unchanged peak widths upon addition of equal levels of a standard.

RESULTS

The levels of the 12 most variable amino acids found in mammary tissue and tumor pools are listed in tables 1–6. The rat representatives comprised 4 metastasizing tumors (all transplanted; table 1) and 7 nonmetastasizing tumors (2 transplanted and 5 DMBA-induced; tables 1, 2). We sampled all tumors at their primary or implantation sites. The nonmetastasizing tumors could be distinguished without overlap from the metastasizing tumors by high accumulations of free glutamine (2,623±845 vs. 765±301 nmol/g of tumor, respectively) and by significant cystathionine pools (212±196 vs. 5±7, respectively). For both amino acids these differences were of the same high significance by the Mann-Whitney test (P=0.01) and by the Wilcoxon signed rank test (P=0.009) (*13*). The high glutamine pool levels were not associated with any maxima or minima in the pool levels of asparagine or of the other nonessential amino acids. Of the transplanted tumors, strains DMBA-4 and MT-449 are the slowest and the fastest, respectively, to appear after transplantation, SMT-2A and TMT-081 are the 2 most metastatic and least differentiated tumors, respectively, whereas MT-449 and MT-100 had been harvested in unusually small and large sizes, respectively. None of these distinctions appeared to be accompanied by major or consistent pool changes. Also, the pool profiles of the tumor centers, which would represent the most circumscribed nutritional supply and the most limited growth, showed only minimal and random statistical differences from the profiles of the tumor peripheries.

Close similarity if not near identity in pool sizes may be noted among the different-sized DMBA-induced tumors of table 2, except for the smallest, whose cellularity was unknown. These tumors had consistently low free hydroxyproline pools. This phenomenon could be due to low endogenous production or turnover of collagen, the absence of hydroxyproline in the casein diet, and poor tumor transport of hydroxyproline.

For a more consistent comparison with the transplanted tumors, the circulating level of hydroxyproline in the blood plasma of a TMT-081-bearing rat was kept at a minimal 20 nmol/ml by feeding the rat a 20% casein diet for 4 days. The hydroxyproline pool of the tumor was still moderate, at 130 nmol/g tumor tissue. Thus the basal hydroxyproline pool in at least 1 transplanted tumor was still sensibly higher than that in the induced tumors.

We further compared the amino acid pools in a relatively old, 20-g TMT-081 rat tumor with the pools of its axillary metastasis and pools in normal rat virgin and lactating mammary tissue (table 3). The postpartum mammary sample may be regarded as involuting since the newborn were probably not nursed. The original implantation site was highly necrotic, and the assayed narrow intact periphery was not firm. Nevertheless, the amino acid pool profile was not notably different from that of the 1.5-g nonnecrotic axillary metastasis, and this profile also resembled the profile of the earlier implant sample in table 1. The glutamine pool level was low, close to the plasma level, whereas the other

TABLE 1.—*Levels of selected amino acid pools of transplanted rat mammary tumors*[a]

Amino acid	DMBA-4	Metastasizing tumors		TMT-081	Nonmetastasizing tumors	
		MT-449	SMT-2A		MTW-9B	MT-100

[a] Values are means (mmol/g tissue) ± SD. A single tumor of each line was harvested from the original implantation site. The whole MT-449 tumor was assayed. For the other tumors, acidic and neutral amino acids were determined in tumor periphery and core samples, and the values were averaged. Basic amino acids were determined only in the tumor peripheries. Animals were fed Purina Laboratory Chow.

nonessential amino acid and hydroxyproline levels were high.

The nonessential amino acid pools were all relatively low in the virgin mammary tissue, but all of them rose during lactation. In all tumor and normal mammary tissue samples, the arginine level was either low or was depleted slightly below plasma levels. Such depletion would be consistent with the vigorous metabolism of arginine and ornithine noted in other species for the production of nonessential amino acids in milk proteins via the ornithine–proline pathway (*14, 15*). There was no evidence of cystathionine or of unusual levels of other nonprotein amino acids in any of the normal rat tissue samples.

In tables 4–6 the free amino acid pools of mouse tumors are compared with those of other tissues. In 2 of 3 spontaneous C3H tumors examined (table 4), the arginine pool was greatly depleted below plasma level. The tumor with the lowest arginine pool also had the highest ornithine level. In an additional experiment, we found the arginine pool levels of 5 spontaneous mammary tumors to be usually depleted, at tumor:whole blood ratios of 1.73, 1.20, 0.67, 0.64, and 0.30.

We also found arginine depletion in the poorly differentiated SMT-F tumor of the DBA/2Ha mouse. At 4 weeks after subcutaneous implantation, the arginine depletion was severe, equaling that in the arginine-destroying organ, the liver, whereas the arginine level was high in the earliest growths (large and small SMT-F tumors, table 5). It is remarkable that at 4 weeks the tumor had accumulated high GABA levels, which is characteristic of neural tissue. In an additional experiment, 6 SMT-F that weighed 0.25–0.9 g at 9 days were found to have small but consistent arginine pool depletions, with tumor-to-plasma ratios of 0.76±0.10 SD. We observed 2 SMT-F of 0.6 and 1.4 g that contained 6 and 34 nmol GABA/g, respectively, and a 3.5-g tumor at 15 days after subcutaneous implant that con-

[a] Tumors are arranged in order of increasing size. Tumors #2 and #5 were from the same animal, and the remainder were all from different animals. Animals were maintained on a 20% casein diet. All but the first tumors were examined histologically and were characterized as well-differentiated adenocarcinomas.

[b] Tumor #1 was omitted from the means.

tained 69 and 126 nmol GABA/g in the tumor periphery and in the more friable interior, respectively. Older tumors contained 300 nmol or more GABA/g. Thus arginine pools were depleted relatively early in the SMT-F and GABA accumulation appeared much later and mainly in the older parts of the tumor.

In the more highly differentiated SMT-S tumor, arginine was not depleted materially at a large tumor size (table 5). In an additional experiment in $CD_{ha}F_1$ females, the SMT-S had depleted tumor-to-plasma arginine ratios of 0.71, 0.50, and 0.72 in 0.3-, 0.4-, and 0.6-g tumors, respectively, and undepleted ratios of 1.05 and 1.10 in 0.5- and 4.0-g tumors, respectively. Thus in this tumor arginine depletion is more characteristic of early growth. SMT-F and SMT-S had high, variable hydroxyproline pools (table 5 and additional data not shown). SMT-F and SMT-S also had slightly elevated glutamine pools, but their significance in these nonmetastasizing tumors is unclear in the absence of metastasizing examples. Cystathionine was present in more than trace quantities in SMT-S and SMT-F, and perhaps even in primary tumors (all nonmetastasizing; tables 4, 5), but it was not present at the levels encountered in the rat tumor counterparts. Cystathionine accumulation may reflect a balance between production and breakdown. Thus in sample 2, table 5, the SMT-F host was slightly cystathioninemic with elevated liver cystathionine, whereas the tumor had lower cystathionine levels than the plasma. β-Alanine, which is low in normal tissues, accumulated at significant-to-high levels in mouse and rat tumors. Taurine accumulated in the slow-growing DMBA-4 rat tumor at an unusually high level characteristic of brain or muscle tissue (*16*). The remaining acid pools were not notably different from those in spleen or liver.

In table 6 we compared the pool profiles of the normal mouse mammary gland without lactation, during lactation, and 2 days after removal of the young (at 11 days postpartum). In the sample taken 2 days after the removal of the young, the breast tissue was centrifuged for 5 minutes at low

temperature to express part of its milk content. Milk has been estimated to comprise three-quarters of the mass of the actively lactating mammary gland and half of the mass after 2 days in involution (*17*). Freshly collected milk itself was depleted in arginine, but it was also low or depleted in almost every other amino acid. In addition to the amino acids shown, the branched chain, aromatic, and sulfur-containing amino acids were virtually abolished in the free form, at levels of 2–17 nmol/ml. Thus most of the free amino acids in the lactating glandular tissue per se must be several times higher than the values shown for the whole gland. The mammary arginine pools were clearly depleted at all stages, most strikingly during active lactation. Arginine breakdown in the rat mammary gland appears to be induced largely during active lactation (*15*), but in the mouse mammary gland, arginine depletion occurred even without milk production. Taurine content appears to be very variable; we observed high levels in the virgin mouse breast. The hydroxyproline pool became extremely high during active lactation. Other nonprotein amino acids were absent or unchanged.

We found all tumors to be virtually collagen-free. This was established from the hydrolysate assays of the proteins of the transplanted tumors DMBA-4, MT-449, TMT-081, MT-100, SMT-F, and SMT-S, of 3 primary DMBA-induced rat mammary tumors, and of 1 spontaneous C3H mammary tumor. Hydroxyproline residues accounted for collagen levels of only 0.1–0.2% of the tumor protein.

DISCUSSION

Intracellular Arginine Pools

Among the most noteworthy characteristics of the free amino acid pools of rodent mammary adenocarcinomas was the observation that arginine pools can be depleted, most commonly in the spontaneous C3H mouse mammary tumor (5/8 tumors). Depletion, comparable to virtual abolition as occurs in the liver, was found in 2 relatively early intact tumors less than 1 cm in diameter and without conspicuous hematomatous areas. In transplanted SMT-F and SMT-S, this depletion was most apparent in established but not always in advanced growth. Arginine depletion is not unique to the tumors, because it also occurred in normal mammary tissue, particularly in the mouse, and during active lactation. In mouse mammary tumors the arginine depletion may be accompanied by heightened levels of ornithine, but this is not consistent. Arginine depletion in the mouse mammary tumor cannot be attributed to poor uptake, because of the nonspecificity of the basic amino acid transport system Ly$^+$ (*18*). The levels of other basic amino acids, lysine and histidine, were the same or up to twice that of the circulating plasma level in the 8 examined spontaneous tumors.

These studies thus show that some tumors can, like the liver, catabolize an amino acid faster than it can be replaced from the plasma. Arginase already present in the normal mammary tissue (*19*), may deplete arginine pools in tumors. Invading macrophages may further contribute high arginase activity as a component of host defense (*20*). In preliminary experiments we found considerable in vitro destruction of arginine in the adherent cells of minced and sieved fragments of a spontaneous C3H mammary tumor, but we found a similar activity in the nonadherent component of the SMT-F transplanted tumor. The differences remain to be resolved. The variable occurrence of spontaneous arginine depletion in mammary adenocarcinomas may explain the contradictory claims for the effectiveness of arginase treatment of these tumors (*21, 22*). Experimental tumors that are already prone to arginine depletion would be the most suitable targets for arginine antagonism, e.g., by canavanine (*23*), or for further arginine depletion by activated macrophages.

GABA and Cystathionine Levels in Rodent Mammary Tumors

GABA and cystathionine, which were found at significant-to-high levels in a number of the mammary tumors, have heretofore been considered virtually unique to neural tissue or neurally derived cells (*7*, *8*). We have shown cystathionine pools to be absent at all functional stages in normal rodent mammary tissue. We have found cystathionine to be present in only relatively moderate quantities in rodent brain, at 28 and 140 nmol/g of the cerebrum and cerebellum of the rat, and at 22 and 55 nmol/g in cerebrum and cerebellum of the mouse, respectively. The cystathionine levels in rat mammary tumors are more comparable to the 400-nmol/g level in the mouse C1300 neuroblastoma (Pine MJ: Unpublished results). Cystathionine can also accumulate in plasma or urine from the reduction or loss of γ-cystathionase activity, either from drug treatment, vitamin B_6 depletion, or inborn errors of metabolism (*24*). γ-Cystathionase commonly becomes depleted or absent in tumors (*25*). This depletion, however, would not explain the association of high cystathionine pools only in the nonmetastatic rat mammary tumors. Moreover, cystathionine pools are generally absent (Pine MJ: Unpublished results) in nonneural tumors, such as L1210 leukemia and B-16 melanoma, that also lack γ-cystathionase. Elevated cystathionine in the nonmetastasizing rat tumors may possibly reflect an early disturbance in sulfur amino acid metabolism associated with tumorigenesis.

Cystathioninuria can also be associated with hepatic metastasis (*26*). Hepatic alteration from metastases could thus account for the significantly elevated cystathionine levels in host liver and plasma found in one SMT-F tumor-bearing mouse. Other less specific neural constituents such as taurine and β-alanine also occurred at unusually high levels in individual mammary tumors.

Amino Acid Markers in Rat Tumors

In the rat tumors, metastatic capacity correlated consistently with a low concentration of free glutamine and with a virtual absence of cystathionine. Many rodent tumors can concentrate glutamine to twice the plasma levels or greater (Pine MJ: Unpublished observations). This ability refutes the notion of a general depletion of glutamine pools in tumors indicated by older qualitative assays (*27*). Arginine appeared to be only marginally depleted in the TMT-081 tumor (table 3). In addition, in a TMT-081 tumor-bearing animal on a 20% casein diet the tumor-to-plasma arginine ratio was also found to be slightly depressed at 0.92. The rat mammary tissue, like that of the cow (*14*), may not rely as heavily on arginine metabolism as do other species for the production of the nonessential amino acid residues of milk protein.

Since all the tumors examined were very low in collagen content, the hydroxyproline pools are likely to reflect the relative concentrative activity of the amino acid transport system(s) for imino acids and glycine (*17*, *28*). This activity may serve as a distinction between autochthonous and transplanted mammary tumors in the rat. The normal mammary gland may also augment this transport system during lactation. The virtual absence of collagen in the mouse and rat mammary tumors would suggest that mesenchymal cells do not contribute substantially to the amino acid pools determined for these tumors. The presence of some stromal material, however, is not precluded, because the SMT-S was relatively resistant to physical dissociation. The SMT-S may produce some cartilagenous component, but this would probably be a product of the tumor cell per se rather than a structure that involves mesenchymal cell participation.

The intracellular pool of nutrients would be expected to depend on, or to be affected by external supplies. The TMT-081 tumor, taken as representative of metastatic rat mammary tumors, has been found to have a lower rate of blood flow than several nonmetastatic representatives (Jirdle R, Kim U: Unpublished observations). Although the individuality of blood supply might be the underlying reason for some of the differences in intracellular pool sizes, a great dependence might be expected to produce more significant variations than those that are actually apparent in the pool profiles of TMT-081 tumor samples taken either from the tumor center, from the periphery, from intact areas, or from areas adjacent to necrosis (tables 1, 2). Rodent mammary tumors may contain large macrophage populations. In a recent study of macrophage content versus metastatic capacity (*29*), the macrophage content of the MADB-100 nonmetastasizing DMBA-induced rat mammary tumor was found not to differ greatly from that of its metastasizing MADB-105 derivative. The same was seen in other metastasizing and nonmetastasizing tumor pairs (*29*). Thus it is unlikely that changes in the macrophage population would consistently explain the amino acid pool differences that distinguish the metastasizing from the nonmetastasizing rat mammary tumors in tables 1 and 2.

Although free amino acids may be easily liberated artifactually, for example at room temperature, the effect is probably minimal on the reported tumor pool values. Thus variations in harvesting the SMT-F and several other tumors that either shortened the harvest time (e.g., exposure of the tumor periphery during anesthesia and excising of tumor directly into sulfosalicylic acid before weighing) or that prolonged harvest (e.g., 10 min of incubation on ice) produced relatively minor pool alterations. Free amino acid pools have been determined in liver and hepatoma by freezing and grinding the tissues in liquid N_2 before extraction (*29*). We have found that freezing in N_2 produced variable levels of free amino acid, equal to or much greater than those obtained by direct acid inactivation (Pine MJ: Unpublished results). The pools of free amino acids in rat liver obtained by freezing in liquid N_2 reported by Moyer and Pitot (*30*) are much higher than our own pools for liver and other organs. Therefore, N_2 freezing may produce artifacts in pool extraction rather than minimize their chances. Although necrosis might also be expected to liberate free amino acids, the similarity of pools from old and young mammary tumors and from areas adjacent to necrosis would suggest that inflammatory cells and the circulation prevent the accumulation of necrotic products. Samples from the frankly necrotic areas of neuroblastomas have reduced levels of marker amino acids such as cystathionine but without the accompaniment of conspicuous increases in other amino acids (Pine MJ: Unpublished results).

Immunomodulation of the Lymphoresponsive Phases of Carcinogenesis: Mechanisms of Natural Immunity[1,2]

Charles H. Evans,[3,4] **Joseph A. DiPaolo,**[3] **Jeffrey A. Heinbaugh,**[3] *and* **Anthony J. DeMarinis**[3]

ABSTRACT—Biphasic modulation of the frequency of 3-methylcholanthrene-induced tumors in relation to increasing immunocompetence of tumor-bearing mice is indicative of lymphoresponsive stimulatory and inhibitory phases of carcinogenesis; components and mechanisms contributing to the paradoxical ability of the native or natural immune system to stimulate as well as to inhibit the development of cancer were identified with the use of an in vitro model of carcinogenesis. Normal NIH/N Syrian golden hamster spleen leukocytes caused a biphasic modulation of UV-irradiated hamster cell morphologic transformation that was dependent on the leukocyte-to-target cell (L:TC) ratio. Whereas low (<50:1) and high (>200:1) L:TC ratios inhibited the transformation frequency, intermediate ratios were less inhibitory and seemingly immunostimulatory. Inhibition alone occurred with antigen- or mitogen-activated leukocytes or with macrophages. An anticarcinogenic lymphocyte hormone, lymphotoxin, eliminated the leukocyte-mediated stimulatory phase; galactose, a lymphotoxin inhibitor, blocked the leukocyte-mediated inhibitory phases. Thus immunoinhibition was mediated through lymphotoxin, and the apparent immunostimulation possibly resulted from immune cell regulation of lymphotoxin activity during the early stages of carcinogenesis.—JNCI 1982; 69:737–740.

Lymphoresponsive stimulatory and inhibitory phases of carcinogenesis have been postulated because the number of tumors in immunologically crippled mice receiving the carcinogen 3-methylcholanthrene increases and decreases with progressive restoration of the immune capacity of the mice (*1, 2*). The same biphasic response occurs in immunoreconstituted mice that receive skin grafts from 3-methylcholanthrene-treated syngeneic mice (*3*). Thus the lymphoresponsive phases are a result of natural physiologic or homeostatic responses by the host rather than a result of carcinogen-induced systemic effects.

The frequency of carcinogen-induced morphologic transformation in cultured Syrian hamster cells can be quantitated within a week after carcinogen treatment (*4, 5*). UV light irradiation and various chemical carcinogens induce neoplasia as indicated by the ability of the transformed cells to produce tumors (*6, 7*). Transformation, moreover, can be irreversibly inhibited by the immunologic hormone lymphotoxin (a lymphokine) (*8*). In the present investigation, Syrian hamster macrophages, spleen lymphocytes, and/or lymphotoxin were cocultivated with carcinogen-treated target cells to characterize the cellular and soluble mediators modulating carcinogenesis. UV radiation was selected as the carcinogen to minimize effects of the carcinogen on the effector leukocytes. The results provide the first demonstration that the lymphoresponsive phases can occur early in carcinogenesis and that the balance between apparent immunoinhibition or immunostimulation may be mediated through lymphotoxin.

MATERIALS AND METHODS

Carcinogen-induced transformation of hamster cells.—In the quantitative HEC transformation assay, secondary culture cells derived [illegible] 13-day-gestation NIH/N Syrian golden hamster fetu[illegible] were seeded at a density of 300 cells/60-mm tissue culture dish in 4 ml D-EMEM containing 10% FBS (*9*) and 25 µg endothelial cell growth supplement (Collaborative Research Inc., Waltham, Mass.) (*10*). One day later, the cells were treated by UV irradiation and incubated in 8-ml medium–serum for 6 additional days. Dishes were fixed and stained and colonies counted and microscopically evaluated for transformed morphology. The cloning efficiency was the ratio of the colonies greater than 2 mm in diameter, and the number of cells plated was expressed as a percentage. Details regarding the administration of UV radiation to the cells were given by DiPaolo and Donovan (*7*).

Addition of leukocytes and lymphotoxin to the transformation assay.—We obtained freshly prepared spleen leukocytes from 4- to 6-month-old healthy male NIH/N Syrian golden hamsters [some having KLH immunity (*8*) and some nonimmunized] by gently teasing spleens to obtain single cell suspensions. We then washed the leukocytes with RPMI-1640 medium, and filtered them through gauze. Alveolar macrophages were obtained by bronchial lavage with 50 ml RPMI-1640 medium per hamster, washed in 50 ml RPMI-1640 medium, and cultured during the transformation assay in the presence of 50 µg gentamicin/ml D-EMEM. Peritoneal macrophages were obtained from mineral oil-induced peritoneal leukocytes (*11*). Peritoneal leukocytes were collected by lavage with 50 ml RPMI-1640 medium per hamster and cultured for 30 minutes in RPMI-1640 medium–10% FBS; the adherent cells were removed with a rubber policeman, washed two times with RPMI-1640 medium, counted, and suspended in D-EMEM. The leukocytes were added to HEC immediately after irradiation, and D-EMEM was adjusted to 8 ml. The antigen KLH at 100 µg/ml was

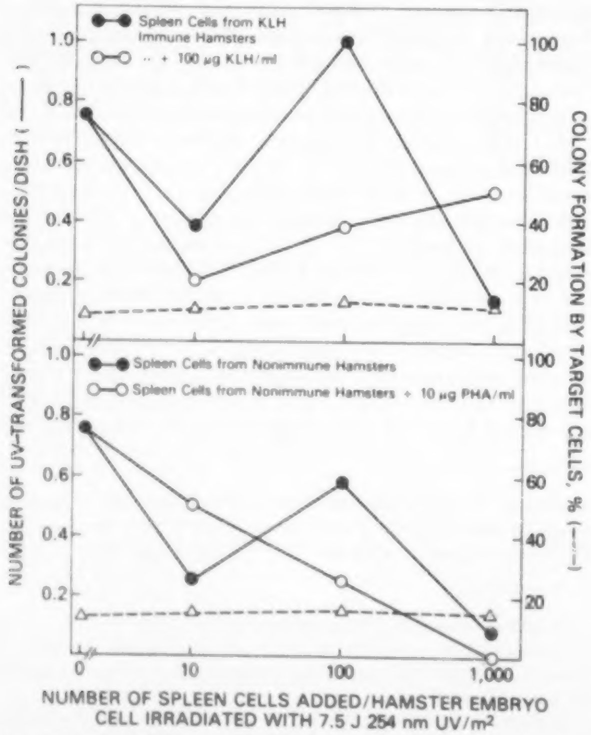
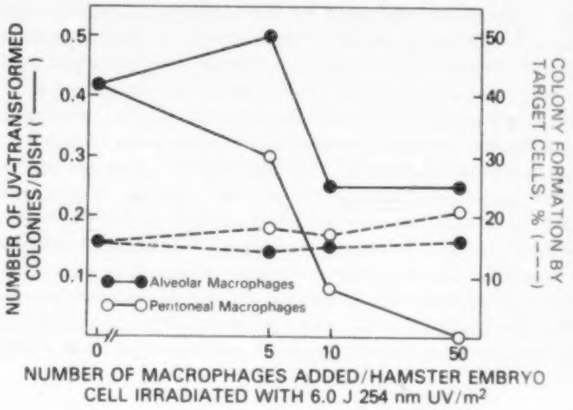
TEXT-FIGURE 1.—Inhibition of carcinogen-induced morphologic transformation ± SEM of Syrian HEC by normal spleen leukocytes. Cells (300) were seeded/60-mm dish in 4 ml D-EMEM containing 10% FBS and 25 µg endothelial cell growth supplement/ml and treated by UV irradiation 24 hr later. Freshly prepared spleen leukocytes from 4- to 6-mo-old male nonimmunized healthy NIH/N Syrian golden hamsters were added to the embryo cells immediately after irradiation, and the culture medium was adjusted to 8 ml. Cells were fixed and stained 7 days after seeding, and the colonies were counted and examined for morphologic transformation.

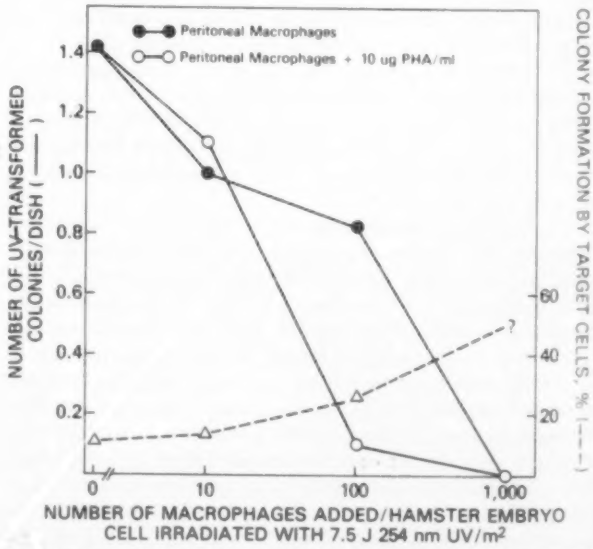


TEXT-FIGURE 2.—Inhibition of morphologic transformation by spleen leukocytes from KLH-immune hamsters with and without KLH antigen stimulation and by nonimmune leukocytes with and without mitogen (PHA) stimulation. Transformation assay was performed as described in text-fig. 1.

included in some KLH-immune spleen leukocyte–HEC cultures. The mitogen PHA at 10 µg/ml was added to some nonimmune spleen leukocyte–HEC cultures. Cells were fixed and stained 7 days after they were seeded and the colonies were counted and examined for morphologic transformation. Lymphotoxin free of detectable interferon antiviral activity was obtained from mitogen-stimulated hamster peritoneal leukocytes, was concentrated by diafiltration with the use of a YM10 membrane, and was added to the HEC immediately after irradiation (*8*). In each experiment, 12 dishes were set up for each carcinogen, leukocyte, chemical, and /or lymphotoxin concentration.



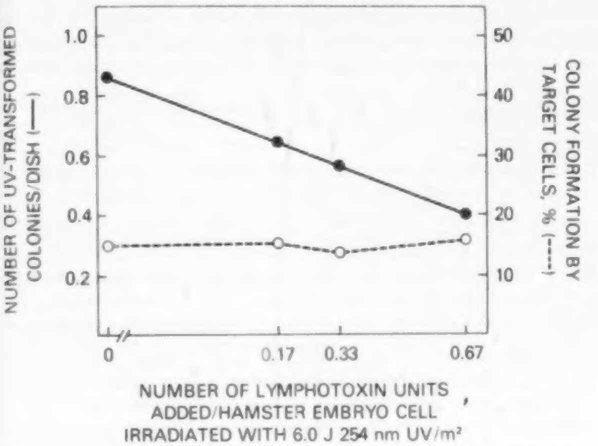
TEXT-FIGURE 3.—Inhibition of morphologic transformation by alveolar and peritoneal macrophages from nonimmune hamsters. Transformation assay was performed as described in text-fig. 1.



TEXT-FIGURE 4.—Inhibition of morphologic transformation by peritoneal macrophages from nonimmune hamsters with and without mitogen stimulation. Transformation assay was performed as described in text-fig. 1. *Question mark* indicates that colonies were too numerous to quantify accurately due to the macrophages serving as a feeder layer at the 1,000:1 effector-to-target cell ratios.

RESULTS

The addition of normal nonstimulated hamster spleen leukocytes to UV-irradiated hamster fibroblasts at effector-to-target cell ratios from 10:1 to 1,000:1 resulted in a biphasic modulation of the transformation frequency of UV-irradiated hamster fibroblasts (text-fig. 1). Transformation frequency was reduced at ratios less than 50:1, approached the UV irradiation only level at ratios approximately 50:1–200:1, and was reduced again at higher effector-to-target cell ratios. Spleen leukocyte modulation of the transformation frequency occurred without cell lethality since the number of colonies was independent of the number of leukocytes. Alteration of the transformation but not the colony-forming frequency demonstrated the specificity of the lymphomodulation for carcinogenesis.



TEXT-FIGURE 5.—Inhibition of morphologic transformation by lymphotoxin. Transformation assay was performed as described in text-fig. 1.

TABLE 1.—*Modulation of normal spleen cell anticarcinogenic activity*

Treatment[a]	Absolute No. of transformed colonies/dish
UV radiation alone	2.1
UV radiation + galactose	1.8
UV radiation + lymphotoxin	0.6[b]
UV radiation + 100:1 spleen cells	1.1[b]
UV radiation + 100:1 spleen cells + galactose	2.1[c]
UV radiation + 100:1 spleen cells + lymphotoxin	0.2[b, c]
UV radiation + 200:1 spleen cells	1.4
UV radiation + 200:1 spleen cells + galactose	1.9
UV radiation + 200:1 spleen cells + lymphotoxin	0.3[b, d]

[a] HEC were UV irradiated with 4.5 J/m^2 and treated with nonimmune spleen leukocytes as described in text-fig. 1. Galactose (1 μM), an inhibitor of lymphotoxin activity, and lymphotoxin (0.3 U/cell) were also included in the assay at the time of spleen cell addition for determination of the extent of participation of lymphotoxin in the biphasic inhibition of transformation. Results are shown for the maximum inhibitory (100:1) and stimulatory (200:1) effector-to-target cell ratios in the experiment.

[b] $P<0.05$ compared to value for UV irradiation alone, by Student's *t*-distribution two-tailed test.

[c] $P<0.05$ compared to value for UV irradiation + 100:1 administered spleen cells, by Student's *t*-distribution two-tailed test.

[d] $P<0.05$ compared to UV irradiation + 200:1 administered spleen cells, by Student's *t*-distribution two-tailed test.

Antigen or mitogen stimulation of spleen leukocytes eliminated the stimulatory phase (text-fig. 2). This suggested that the stimulatory phase was mediated through lymphocytes. This hypothesis was confirmed by macrophage modulation of the transformation frequency inasmuch as only the inhibitory phase was observed in the presence of macrophages (text-figs. 3, 4). The addition of lymphotoxin, a lymphokine that directly inhibits transformation (text-fig. 5), eliminated the immunostimulatory phase (table 1). However, galactose, a critical sugar in the glycopeptide receptor to which lymphotoxin binds (*12*), blocked the inhibitory but not the stimulatory phase (table 1). Thus: 1) Inhibition was mediated through lymphotoxin, 2) the lymphostimulatory phase resulted from modulation of lymphotoxin activity, and 3) both lymphoresponsive inhibitory and stimulatory phases were present early in carcinogenesis.

DISCUSSION

The components contributing to the lymphoresponsive phases of primary autochthonous tumor growth (*1–3*) have been cryptic as has been the carcinogenic stage(s) affected by these homeostatic responses. This is partly due to the complexity of carcinogenesis, which proceeds through many stages commencing with carcinogen exposure and culminating with the appearance of an observable tumor (*13*). During neoplastic development a multiplicity of immunobiologic alterations capable of eliciting a host response can occur at the level of the developing tumor or target cell, including antigen formation, alteration and/or deletion (*14*), and susceptibility to natural leukocyte (*15–17*) and lymphokine cytotoxicity (*18*). Some of these changes can develop very early and others quite late during carcinogenesis. For example, neoantigens have been detected as early as 18 hours after 3-methylcholanthrene exposure (*19*), whereas development of susceptibility to the growth inhibitory activity of lymphotoxin may require many months (*18*). Growth of tumor cells may also be stimulated by normal naturally or specifically immune lymphocytes, possibly due to the presence of fetal antigens or undefined components on the tumor cells (*20–22*).

Immune regulation is a complex interaction or balance among helper, suppressor, and natural cytotoxic and killer leukocytes (*23, 24*), lymphokines (*25*), and other hormone regulators (*26*). UV irradiation, for example, both induces neoplasia and enhances suppressor leukocyte activity, thus permitting the growth of highly antigenic tumors (*27, 28*). Corticosteroids are immunoinhibitory and can also directly modulate carcinogenesis at the level of the target cell (*29*). Interferon stimulates natural killer cell activity while it decreases target cell sensitivity to natural killer destruction (*30*). Interferon can inhibit carcinogenesis (*31*), but it can also stimulate morphologic transformation of the murine C3H/10T½ cell line (*32*). Lymphotoxin, in contrast, has little or no effect on the tumor inhibitory activity of macrophages, killer lymphocytes, or other naturally cytotoxic lymphocytes (*11*), but it increases target cell sensitivity during carcinogenesis to natural killer cell destruction (*33*), reversibly inhibits growth of most tumor cells (*11, 34*), and irreversibly inhibits carcinogen-induced morphologic transformation (*8*). Therefore, many points or stages in carcinogenesis are subject to homeostatic control by the normal immune system, and the apparent immunostimulation of the lymphoresponsive phases of carcinogenesis in vivo may reflect in part the immunomodulation of lymphotoxin.

Lymphotoxin Prevention of Diethylnitrosamine Carcinogenesis In Vivo[1,2]

Janet H. Ransom,[3,4] Charles H. Evans,[3] *and* Joseph A. DiPaolo[3]

ABSTRACT—Development of intervention measures to control cancer would be facilitated by being able to monitor in vivo carcinogenesis by in vitro quantitation of early indices of neoplastic transformation to assess the in vivo effectiveness of preventative-therapeutic measures. Pregnant Syrian golden hamsters were used in an in vivo-in vitro transplacental model of carcinogenesis to determine the extent that in vivo administration of immunologic hormone preparations along with chemical carcinogen would prevent morphologic transformation assessed in vitro. Pregnant hamsters at 10–11 days of gestation were given injections ip of 3 mg diethylnitrosamine (DENA)/100 g body weight and were killed 2 days later when fetal cells were seeded for colony formation. The frequency of morphologically transformed colonies was assessed after 7 days of growth. Cloning efficiency and mean transformation frequency after DENA exposure were 3.6% and 1×10^{-4} per cell seeded, respectively. The ip injection of an immunologic hormone preparation reduced the transformation frequency by 46%. The hormone preparation, containing 10,000 U of lymphotoxin but no detectable interferon, was the ultrafiltered lymphokines (>10,000 mol wt) from phytohemagglutinin-stimulated hamster peritoneal leukocytes. The effect of lymphotoxin on cocarcinogenic exposure of fetal cells to DENA in vivo followed by X-irradiation in vitro was also determined. Cells exposed to 250 rad in vitro had a cloning efficiency of 0.5% and a transformation frequency of 0.4×10^{-4} per cell seeded. After DENA injection and X-irradiation, the transformation frequency increased to 1×10^{-4} and was inhibited 64% by lymphotoxin in vivo. Thus immunologic hormones (e.g., lymphotoxin) can prevent carcinogenesis in vivo. Furthermore, in vitro quantitation of transformation is a rapid means for evaluating therapeutic and autochthonous effector mechanisms for their ability to prevent or otherwise modulate carcinogenesis in vivo.—JNCI 1982; 69:741–744.

Cancer prevention may be achieved by active intervention at various stages during the carcinogenic process to prevent and/or reverse the development of neoplasia (*1*). Intervention measures, exclusive of those eliminating the causative agent, include control of carcinogen metabolism (*2, 3*) and suppression of preneoplastic cells by immunologic (*4–7*), hormonal (*8, 9*), and nutritional (*10*) factors. One type of immune mediator, the immunologic hormones (including lymphokines, monokines, interleukins, and interferons) is of particular interest as an anticarcinogenic agent inasmuch as these hormones have or mediate antitumor activity in vivo (*11–13*) and anticarcinogenic activity in vitro (*14–16*).

Two immunologic hormones with direct-acting anticarcinogenic activity are lymphotoxin (*14, 17*) and interferon (*16, 18*). Lymphotoxin may be either cytolethal or cytostatic for tumor cells (*19*), can irreversibly prevent carcinogenesis in vitro without inhibiting cell growth (*14*), and can induce a heightened susceptibility in preneoplastic and neoplastic cells to natural killer cell-mediated cytotoxicity (*20*). In this investigation lymphotoxin was administered with a chemical carcinogen in vivo for evaluation of lymphotoxin anticarcinogenic activity in vivo. A combined in vivo–in vitro method utilizing transplacental DENA exposure of pregnant Syrian golden hamsters was selected for assessment of the in vivo anticarcinogenic activity of lymphotoxin. This method was chosen because the effects of in vivo carcinogen exposure can be rapidly quantitated by measurement of morphologic transformation in vitro (*21, 22*). DENA, a known transplacental carcinogen in hamsters, causes the progeny to develop respiratory tract tumors (*23*). In the combined in vivo–in vitro assay, carcinogen-exposed fetal cells are subpassaged and plated for colony formation. Morphologically transformed colonies result that, when isolated, produce tumors in Syrian hamsters and athymic nude mice (*21, 22, 24*). Thus the extent to which lymphotoxin prevents carcinogenesis in vivo was determined by in vitro measurement of morphologic transformation of cells that had been exposed transplacentally to lymphotoxin and DENA.

MATERIALS AND METHODS

Combined in vivo–in vitro carcinogenesis assay.—Pregnant NIH/N Syrian golden hamsters at days 10–11 of gestation received ip injections of 3 mg DENA/100 g body weight (*21, 22*). Two days later fetuses were excised, the heads and viscera were removed, and the carcasses were mechanically minced and dissociated into a single cell suspension by trypsinization (*25*). Then 2,000 cells were seeded per 60-mm tissue culture dish in 8 ml of modified Dulbecco's medium containing 10% fetal bovine serum, 3×10^{-6} *M* thymidine, 3×10^{-5} *M* hypoxanthine (Calbiochem-Behring Corp., La Jolla, Calif.), and 50 µg endothelial cell growth supplement/ml (Collaborative Research Inc., Waltham, Mass.) (*26*). Cells were incubated 7 days for colony formation at 37°C in a 10% CO_2–water-saturated atmosphere of compressed air purified by PHARM-AIR (Pall Trinity Micro Corp., Cortland, N.Y.). Colonies were fixed in methanol, stained with Giemsa, enumerated on an Artek model 880 counter (Artek Systems Corp., Farmingdale, N.Y.), and examined micro-

scopically for morphologic transformation, a random piled-up layering of cells not observed in non-carcinogen-exposed cells (*21, 26*). For each experimental treatment 120 dishes were examined and quantitated. For some experiments 2×10^6 fetal cells suspended in 2 ml of medium/100-mm dish were X-irradiated with 250 rad, immediately before being seeded, with a Torex model 120 X-ray machine (Torr X-ray Corp., Van Nuys, Calif.) (*15*). After X-irradiation 9×10^3 cells were seeded per 60-mm dish.

Lymphotoxin preparation, assay, and in vivo administration.— Lymphotoxin was prepared by incubation of 10^7 Syrian hamster mineral oil-induced peritoneal leukocytes (*14*) in RPMI-1640 medium containing 100 μg phytohemagglutinin/ml (*7*). After 24 hours the cell-free medium was collected, aseptically diafiltered against phosphate-buffered saline, and concentrated tenfold with an Amicon diafiltration apparatus with a 10,000 nominal molecular weight including YM10 membrane (Amicon Inc., Danvers, Mass.). The number of lymphotoxin units was determined by a radionuclide released assay in which 1 U of lymphotoxin caused the release of 50% of the ^{3}H from [^{3}H]thymidine-labeled murine αL929 cells (*19*).

Lymphotoxin preparations did not contain detectable levels of interferon as assayed by Bio-Fluids, Inc., Rockville, Md., with the use of a semimicrocytopathic effect-reading method ([illegible]) in which interferon units represented the dilution causing a 50% inhibition of bovine vesicular stomatitis virus cytopathic effect in a benzo[*a*]pyrene-transformed Syrian hamster cell line (*14*). The sensitivity of this assay is 5 interferon units.

The anticarcinogenic activity of lymphotoxin preparations administered in vivo was determined by inhibition of morphologic transformation. At the time of DENA injection, pregnant hamsters were also given 10,000 U of lymphotoxin in 0.5 ml ip or 500 U in 0.1 ml iv. Concentrated lymphotoxin preparations at 20,000–30,000 U lymphotoxin/ml were diluted with phosphate-buffered saline to deliver the appropriate dose. Four different preparations were used.

RESULTS

Fetal cells from individual normal hamsters were seeded at various densities to determine the optimal number of colonies for examination. For each dish 60–90 colonies were desired, and with 2,000 cells per dish 70–80 colonies ordinarily result. When cells from 4 normal hamsters were seeded at this density, only nontransformed colonies were observed.

When fetal cells were exposed transplacentally to DENA, the average transformation frequency and cloning efficiency for 13 pregnant hamsters were 1.0×10^{-4} transformants/cell seeded and 3.6%, respectively (table 1). Cells from nontreated animals had the same cloning efficiency as did those from carcinogen-treated animals. An average of 23 total transformants in 120 dishes examined from each DENA-treated animal was observed. This number is sufficiently large and reproducible (an SEM of 1.3) to allow for detection of significant differences in the transformation frequency produced by in vivo intervention measures.

Table 1.—*Morphologic transformation frequency of Syrian hamster cells exposed transplacentally to DENA*[a]

Animal No.	Cloning efficiency, %	Total transformants/120 dishes	Transformants/colony, $\times10^{-3}$	Transformants/cell seeded, $\times10^{-4}$

[a] Pregnant hamsters at 10–11 days of gestation were given ip injections of 3 mg DENA/100 g body wt 2 days before fetuses were removed and trypsinized, and 2,000 cells were seeded per 60-mm dish.

The in vivo treatment of hamsters ip with 10,000 U or iv with 500 U of lymphotoxin simultaneously with DENA exposure resulted in 43 and 26% inhibition of the transformation frequency, respectively (table 2). The similarities in cloning efficiencies indicate that the reduction of the transformation frequency was not due to a decrease in colony formation.

The cocarcinogenic exposure of cells to DENA in vivo and X-irradiation in vitro was examined to determine whether combined treatment would enhance the transfor-

Table 2.—*Lymphotoxin in vivo inhibition of DENA-induced morphologic transformation*[a]

Animal No.	Total transformants/120 dishes	Transformants/cell seeded, $\times10^{-4}$	Inhibition, %[b]

	81-31	37	0.3	
Mean ± SE		32±5.6	0.31±0.05	64±5[c]

[a] The 4 treatment groups consisted of hamsters at 10–11 days of gestation either untreated or given injections ip of 10,000 U of lymphotoxin, 3 mg DENA/100 g body wt, or both lymphotoxin and DENA. Two days later fetuses were removed, trypsinized, and X-irradiated with 250 rad, and 9,000 cells were seeded per 60-mm dish.

[b] Compared to X-irradiation.

[c] Compared to DENA + X-irradiation; $P<0.05$ by Student's *t*-test.

mation frequency and the extent to which lymphotoxin would prevent this transformation (table 3). When fetal cells were exposed to 250 rad of X-irradiation alone in vitro, the cloning efficiency was reduced to 0.5%. However, when 9×10^3 cells were seeded per dish, an equivalent number of colonies resulted as in the DENA experiments. X-irradiation alone at the time of cell seeding induced a transformation frequency of 0.4×10^{-4}/cell seeded, which was unaffected by 10,000 U of lymphotoxin ip 2 days before X-irradiation. With DENA plus X-irradiation the transformation frequency increased to 1×10^{-4} compared to that seen in cells only X-irradiated. This cocarcinogenic exposure was inhibited 64% by in vivo ip administration of 10,000 U of lymphotoxin. After lymphotoxin the transformation frequency was similar to that observed following exposure of cells to lymphotoxin and X-irradiation or to X-irradiation alone (table 3).

DISCUSSION

This investigation demonstrates two important points: *a*) Lymphotoxin is anticarcinogenic in vivo and *b*) the efficacy of potential in vivo modulators of carcinogenesis may be evaluated by in vitro measurement of morphologic transformation. The immunologic hormone preparation that inhibited carcinogenesis in this study contained lymphotoxin but no detectable interferon. Of the other possible lymphokines present, only lymphotoxin has been identified individually to be anticarcinogenic (*17*). Hamster lymphotoxin has been shown to inhibit chemical-induced and UV radiation-induced carcinogenesis in vitro (*14, 15*). Hamster lymphotoxin purified by isoelectric focusing was also anticarcinogenic in vitro, which provided additional evidence that the direct-acting anticarcinogenic activity is due to lymphotoxin (*15*).

In vivo administration of hamster lymphotoxin purified by isoelectric focusing also inhibits γ-irradiation-induced transformation, as assessed by measurement of morphologic transformation with inhibition varying directly with lymphotoxin concentration (*29*). Future investigations will be required to determine if other lymphokines also possess direct and/or indirect anticarcinogenic activities in vivo. If other lymphokines with anticarcinogenic activity are present in hamster lymphotoxin preparations, they have isoelectric pH's, stability upon storage, and fractionation characteristics similar to those of hamster lymphotoxin.

Most animal models for carcinogenesis require carcinogen treatment followed by monitoring of tumor development, a process extending from months to years. Therefore, the use of the rapid quantitative system described herein is an invaluable addition to protracted in vivo assays for identification of substances-effectors and for determination of the optimal conditions for their anticarcinogenic activity. Expression of morphologic transformation correlates with the neoplastic potential of cells, inasmuch as cells derived from isolated transformed colonies produce tumors when these cells are injected into hamsters or athymic nude mice (*21, 22, 24, 30*). Thus the reduction of the transformation frequency measures the prevention of morphologic transformation, an early step in carcinogenesis, and is a direct measure of the prevention of carcinogenesis.

One difference in the transplacental transformation procedure followed in the present investigation from the procedures used by others (*21, 22*) is that in the present investigation cells, instead of being subcultured, were seeded directly from the animal for colony formation. Quarles et al. (*22*) reported a transformation frequency of 0.01 transformant/colony on cells subcultured three to ten times before being seeded for colony formation. We observed without subculture a somewhat lower number of 0.0027 transformants/colony, a number in agreement with that of DiPaolo et al. (*21*), who reported that the transformation frequency increases with subculture of transplacentally exposed fetal cells. For these reasons the transformation frequency per cell plated directly from the fetus(es) more closely approximates the number of cells affected by the carcinogen in vivo and is a better indication of the effectiveness of in vivo intervention measures.

When DENA treatment in vivo was coupled with a cocarcinogenic X-irradiation exposure in vitro, the frequency of transformation was enhanced compared to that seen in cells treated only with X-irradiation. The cocarcinogen transformation frequency was also considerably higher than that resulting from DENA alone when the toxicity due to X-irradiation is considered (tables 1, 3). Lymphotoxin inhibited the cocarcinogen-induced transformation but had no effect on transformation induced by in vitro X-ray exposure alone. This observation suggests that there may be at least three populations of transformed cells: one transformed by in vivo DENA, one transformed by in vitro X-irradiation, and one that is initiated by in vivo DENA but transformed only after an additional in vitro cocarcinogenic insult by X-irradiation. The two populations susceptible to in vivo lymphotoxin anticarcinogenic activity are those induced in vivo by DENA. Although lymphotoxin directly inhibits X-ray-induced transformation in vitro (*15*), the in vivo lymphotoxin treatment had no effect on the in vitro X-ray transformation frequency (table 3). The temporal relationship of lymphotoxin treatment to X-ray exposure in the presence of increasing numbers of fetal target cells (in vivo growth) may be responsible for the disparity in results. Distinct carcinogen and lymphotoxin antitransformation–temporal interrelationships have been observed when cells are pulsed for varying periods with lymphotoxin in vitro before (*31*) or after (*14*) carcinogen exposure. Similar relationships most likely occur in vivo. Therefore, cells that are initiated and receptive to the appropriate cocarcinogenic insult and completely transformed cells are at this premalignant state susceptible to immune regulation. Intervention measures thus have the potential to prevent the continued development of neoplastic transformation in cells having received a complete or an initiated carcinogenic insult.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Advances in Pediatric Oncology Seminar

The Association of Pediatric Oncology Nurses will sponsor this meeting entitled "Care of the Child and Family" to be held in New York City on October 7-8, 1982. The program will focus on assessment and management of pain in children, alternative strategies of coping with pain and chronic illness, and long term psychological effects of illness in children.

For brochure and registration forms please contact Ms. N. Houlihan, APON Program, 511 E. 80th Street, New York, New York 10021.

Thirty-Sixth Annual Symposium on Fundamental Cancer Research

"Cancer Invasion and Metastasis" is the subject of this symposium to be held at the Shamrock Hilton Hotel in Houston, Texas, on March 1-4, 1983. The symposium will consider recent developments in the biology of tumor metastasis formation and investigate the possible contributions of these developments to cancer treatment. Program topics will include tumor cell properties and metastasis, tumor invasion, tumor heterogeneity, host factors and metastasis, and therapy of metastasis.

For additional information please contact the Office of Conference Services, Box 18, M. D. Anderson Hospital and Tumor Institute, 6723 Bertner Avenue, Houston, Texas 77030 (telephone: 713-792-2222).

Twenty-Fourth Postgraduate Institute for Pathologists in Clinical Cytopathology

This program, designed for pathologists who are certified (or qualified) by the American Board of Pathology (PA), or their international equivalents, will be given at The Johns Hopkins University School of Medicine and The Johns Hopkins Hospital, Baltimore, Maryland, on April 18-29, 1983. The course will provide an intensive refresher in all aspects of the field of clinical cytopathology, with time devoted to newer techniques, special problems, and recent applications. Topics will be covered in lectures, explored in small informal conferences, and discussed over the microscope with the faculty. Self-instructional material will be available to augment at individual pace. A loan set of slides with texts will be sent to each participant for home-study during March and April before the course begins.

Approval has been granted for 125 credit hours in AMA Category I. Application should be made before February 2, 1983. For additional details please write to Dr. John K. Frost, 610 Pathology Building, The Johns Hopkins Hospital, Baltimore, Maryland 21205.

Accredited Visiting Faculty Program on Colorectal Cancer

An accredited Visiting Faculty Program that will give primary care physicians around the country access to the latest clinical information on colorectal cancer was announced recently. This program is a key element of a 2-year course entitled "Colorectal Cancer: Essentials for Primary Care Physicians." The program is accredited for up to six CME credit hours and is being presented without charge by an independent group of experts in gastrointestinal and family medicine. Like other elements of the course, the Visiting Faculty Program is sponsored by the Office of Continuing Medical Education of Memorial Sloan-Kettering Cancer Center.

A five-member Editorial Board directs the course. Dr. Sidney J. Winawer, Chief of the Gastr[illegible]terology Service at Memorial Sloan-Kettering Cancer Center is Execu[illegible]itor, and 25 nationally recognized authorities comprise the balance of [illegible]e Visiting Faculty. The complete program is comprised of two parts: part 1 focuses on disease and diagnosis, and part 2 focuses on case finding and management. Each part consists of a lecture supported by slides, a discussion session, and a monograph for independent study and later referral. The Visiting Faculty will address audiences comprised mostly of primary care physicians at hospitals, medical schools, and medical association meetings throughout the United States.

Developed and produced by Health Learning Systems, Inc., under an educational grant from SmithKline Diagnostics, Inc., the course is provided in cooperation with the American Cancer Society, the American Society for Gastrointestinal Endoscopy, The American Society of Colon and Rectal Surgeons, The International Workgroup on Colorectal Cancer, and the National Cancer Institute. For additional information about the program please contact Ms. Barbara Anderson, Visiting Faculty Program Coordinator, 200 Broadacres Drive, Bloomfield, New Jersey 07003 (telephone: 201-338-3615 or 800-526-6312).

Journal of the National
Cancer Institute

October 1982
Volume 69
Number 4

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department. Use of funds for printing this periodical has been approved by the Director of the Office of Management and Budget through August 30, 1985.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols; *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40:2083-2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221-245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends, and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3-10/Ann Intern Med 1979;90:95-99/Br Med J 1979;1:532-535/ or Lancet 1979;1:428-430).

Sheep Lung Carcinoma: An Endemic Analogue of a Sporadic Human Neoplasm[2,3]

The increase in the incidence of lung tumors, which has become the leading cause of death from cancer in humans, emphasizes the importance of determining the frequency and nature of lung cancer in experimental animals. Also, the search for and the establishment of spontaneous host-lung tumor systems in other outbred species may prove to be relevant to the study of the etiology, pathogenesis, and immunologic behavior of lung cancer and the response of this cancer to clinical therapy in humans. The comparative method has, of course, long been recognized as an essential and, indeed, an unavoidable approach to the study of human diseases; the names of Koch, Pasteur, and Sigurdsson are sufficiently illustrative and convincing.

FATAL PROLIFERATIVE LUNG DISEASES IN SHEEP

In contrast to the prevalence of primary neoplasms of the lungs in humans, primary neoplasms of the lungs in domestic animals are rare. Sheep are exceptional in having two fatal proliferative lung diseases distributed worldwide. These diseases are 1) pulmonary adenomatosis, which exhibits all the criteria included in the definition of bronchoalveolar cell carcinoma, and will, therefore, be the topic of this editorial, and 2) maedi disease, manifested by typical interstitial proliferation of the lymph aggregates confined to the lungs, a disease as yet unrevealed in humans.

METASTATIC AND CONTAGIOUS PROPERTIES OF SPC

Sheep pulmonary adenomatosis, also called "jaagsiekte" (Dutch *jaag*—"to drive"; *siekte*—"sickness") or "SPC," is characterized by tumor cell growth in the lungs with metastases in the pulmonary and mediastinal lymph nodes (*1–7*). Metastases in the mesentery lymph nodes and visceral organs have also been reported (*5, 6, 8–10*). The symptomatology and macroscopic pathology of this disease were first recorded in scientific publications toward the end of the 19th century (*2*). This naturally occurring malignant disease occurs in most breeds of sheep and in most countries (*2, 8, 10, 11*). Epidemologic and experimental evidence indicates that this neoplasm is horizontally transmitted in nature (*2, 8, 11, 12*).

Most reports on SPC until 1970 (*8*) were in general agreement with respect to the clinical signs, epidemiology, and gross pathology of SPC. The variations in histopathologic interpretations can now be attributed to the stage of development of the tumor, i.e., whether the tumor is early or advanced. However, as far as the etiology was concerned, little was known then about the nature of the putative infectious agent suspected to be involved, although the evidence incriminated "a virus" (*8*).

Histopathologically, the neoplastic cells (cuboidal or columnar) may be arranged in short rows, layers, and acinar or papillary structures or clusters and appear to arise from alveoli, alveolar ducts, and bronchioles (*2, 5, 7, 8, 12–14*). Our first ultrastructural examinations of SPC (*4*) indicated that the neoplastic cells are derived from terminal bronchiolar epithelial cells and from type II alveolar epithelial cells (also called "type B alveolar cells" or "granular pneumocytes"). Our diagnosis was confirmed by others (*15*).

Metastatic lesions anywhere in the body resemble the primary lesions histologically and ultrastructurally (*5, 6, 8, 13, 16, 17*). Various stages of neoplastic expression, ranging from "alveolar epithelialization" to poorly differentiated adenocarcinoma, can be detected in the same tumorous lung of a clinically ill animal (*13, 14, 18*). Most neoplastic structures are composed of neoplastic cells that contain glycogen granules and cytosomes characteristic also of undifferentiated, embryonal lung epithelium. Apart from the alveolar epithelialization, the marginal alveoli surrounding the tumor mass are usually lined by a single layer of relatively well-differentiated cuboidal or columnar cells rich in glycogen granules. In many of these alveoli, papillary projections of the septum and the transformed epithelium into the lumina may plug the bronchoalveolar pathway within the tumor mass. Intensely proliferating cores, sheets, or nests of anaplastic epithelial cells are seen.

HUMAN BRONCHOALVEOLAR CELL CARCINOMA AND SPC SIMILARITIES

The overall tumor architecture and the ultrastructure of the neoplastic cell, including the metastasis, warranted the classification of SPC as a bronchoalveolar cell carcinoma (*7*), strikingly resembling the human bronchoalveolar carcinoma (*7, 19–21*). Both diseases originate in the periphery of the lung and tend to grow within the lung for a prolonged period, terminating in a late metastatic process. In the human tumor cell, as in the sheep tumor cell, apical mucin granules, tonofibrils, microvilli, and cytosomes are found. In domestic animals, bronchiolar and mainly peripheral ade-

Editor's note: Periodically, the Journal publishes guest editorials as a means of transmitting to investigators in cancer research the essence of current work in a special field of study. The Board of Editors welcomes suggestions for future editorials that succinctly summarize current work toward a clearly defined hypothesis regarding the cause or cure of cancer.

nocarcinomas are undoubtedly the most prevalent lung neoplasms; epidermoid and anaplastic carcinomas are rare. Perhaps the situation regarding the type of lung tumors encountered in animals now is similar to that seen in human beings decades ago (*10*). However, at the last World Congress of Pathology, the Panel on Lung Tumors in Man discussed the cause of the recent increase in incidence of human bronchoalveolar cell carcinoma but came to no conclusions.[4]

EARLY TRANSMISSION EXPERIMENTS IN SPC

There has been general agreement that this neoplasm in sheep is horizontally transmitted. As early as 1904, Robertson (*22*) suggested that this natural disease was moderately contagious and emphasized that once it commenced in a flock, the disease was apt to continue and become more widespread. In 1929 De Kock (*1*) further substantiated these findings by exposing healthy sheep to infected animals. A number of these exposed sheep developed SPC. Dungal (*3*) and Dungal et al. (*12*) repeated this experiment in Iceland (*3, 12*). Dungal (*3*) using two methods also proved that the exhaled respiratory air of an affected sheep may contain the infectious agent. The Icelandic epizootic studies by Dungal (*3*) and Dungal et al. (*12*) and the studies by Tustin (*2*) in South Africa left little doubt that horizontal transmission occurs in nature. The disease typically appears as multiple cases in a single herd, whereas in other flocks it may be absent for many years (*2, 17*).

VIRUS DEMONSTRATION IN SPC

A decade ago, we first reported that virus particles morphologically similar to RNA tumor viruses (retroviridae, i.e., clusters of intracytoplasmic A and budding C-type particles) are present in situ in SPC (*4*). These electron microscopic findings were confirmed more recently by other authors (*23*). In addition to the retrovirus association with SPC, herpesvirus-like particles were found in tissue cultures of alveolar macrophages and lung tissues of SPC-diseased animals (*24, 25*). Furthermore, this herpesvirus could be transmitted to normal cultures (*26–28*). However, attempts to produce neoplasms with this agent have been unsuccessful (*29*). The observations of the presence of retroviruses were complemented by our findings that extracts of sheep lung tumors contain particles with a density of 1.15–1.20 g/ml, having the characteristics of a reverse transcriptase in association with a 60–70S RNA (*30*).

INDUCTION OF SPC BY VIRUS PREPARATIONS

The presence of a reverse transcriptase-producing agent in SPC (*30*) was reconfirmed (*29*). When sheep were given this fraction endobronchially, adenomas developed in 2 of 4 of these animals (*29*). More recently, pulmonary adenomatosis was transmitted to newborn lambs by inoculation of the microsomal fraction of a cytoplasmic extract of cultured SPC tumor cells or tumor tissue (*31*). We previously examined by electron microscopy aliquots of equilibrium density gradient-purified material from a primary lung tumor and normal lung tissue and tested them for the presence of reverse transcriptase and oncogenicity. We demonstrated that sections from the 1.15- to 1.20-g/ml density regions of the tumor material contained reverse transcriptase activity and possessed morphologically typical C-type "mature" and "immature" retroviruses (*30*). Normal adult sheep inoculated in the lungs last year with these virus-containing fractions developed the typical proliferating neoplasm after 1 year (*32*).

In summary, the electron microscopic observation of retrovirus in the lungs of sheep bearing SPC (*4, 14, 17, 23*) and the detection of particles with reverse transcriptase (*30, 29*) together with recent infectivity studies (*29, 31, 32*) indicate a retrovirus etiology of SPC. Notwithstanding the findings of close morphologic similarities between human bronchoalveolar carcinoma and SPC, we still do not know whether the diseases are etiologically related.

DIFFERENTIATION OF SPC AND MAEDI

Maedi (sheep progressive interstitial pneumonia), the second lung disease of sheep and frequently associated and occasionally confused with SPC, is also caused by a C-type retrovirus (*32–34*). The relationship between the C-type retrovirus of SPC and the maedi–visna C-type virus was tested by molecular hybridization, which revealed no sequence homology (*35*). This finding indicates that the maedi–visna virus is not implicated in the etiology of SPC, which complements findings in numerous earlier studies in which striking differences in clinical symptoms, pathology, serology (*32*), and histopathology were found.

COMMENTS WITH REGARD TO FUTURE STUDIES

Studies on SPC, a spontaneous, natural animal model, may aid in acquiring a better understanding of the pathogenesis, natural history, epidemiology, and host susceptibility of the disease and may lead to the selection of agents and modalities for chemotherapy in experimental animals and humans.

The etiologic demonstration of C-type retrovirus particles in this naturally occurring neoplasm extends the range of virus–tumor host systems to the ovine species and from leukemia–sarcoma and mammary tumors to lung epithelial tumors, i.e., to the epiendoderm, a major embryonal layer in human neoplasia.

Studies on Carcinogenesis of Human Prostate. II. Long-Term Explant Culture of Normal Prostate and Benign Prostatic Hyperplasia: Light Microscopy[1,2,3,4]

Hayato Sanefuji,[5,6] **Barry M. Heatfield,**[5] **Benjamin F. Trump,**[5,7] *and* **John D. Young, Jr**[5,8,9]

ABSTRACT—Light microscopic and histochemical changes in normal human prostate and benign prostatic hyperplasia (BPH) during long-term explant culture were characterized. Normal human prostate obtained at immediate autopsy of young adults or BPH obtained at the time of surgery were maintained in explant culture as long as 24 weeks. Morphologic alterations in glandular epithelium and stroma in response to culture conditions were assessed by light microscopy and histochemistry of mucosubstances. The histologic and histochemical responses of normal prostate and BPH to in vitro conditions were essentially identical. Within 1 week, secretory epithelial cells became necrotic and sloughed into acinar lumina. Remaining epithelial cells proliferated, repopulated acinar structures, and migrated onto explant surfaces forming a new well-differentiated epithelium characterized by synthesis and secretion of neutral and acidic mucosubstances. During subsequent periods in vitro, synthesis and secretion of mucosubstances gradually diminished whereas the stroma and deep glandular structures became necrotic. Our observations suggest that cells comprising the new epithelium in cultured explants of normal human prostate and BPH are derived from prostatic basal cells.—JNCI 1982; 69:751-756.

Spontaneous adenocarcinoma of the prostate is the most common malignant neoplasm in the adult male and the third most common cause of death from cancer in the United States; only bronchogenic and colorectal carcinomas are more common causes of death. Despite numerous studies of the disease, little progress has been made in understanding the etiology, histogenesis, clinical behavior, and other features of this important neoplasm. Clearly, a suitable model of this disease is needed.

However, the validity of extrapolation from animal models of prostatic adenocarcinoma to the human neoplasm is questionable, and the need for models that are based on human tissues has been recently emphasized (*1-3*) despite inherent difficulties. For example, induction of adenocarcinoma in prostatic tissue of humans can only be done in vitro, with subsequent xenotransplantation for the assessment of tumorigenicity. However, one objection to this approach has been that human prostate tissue usually available for such studies is obtained from surgical specimens of BPH from older patients, which is *not* normal prostate (*1*). Moreover, numerous authors report maintenance of human prostate in explant culture for relatively short periods, usually less than 2 weeks (*4-10*); others report maintenance for periods of 6 weeks (*11*) to many months (*12*). However, few details are available with respect to morphologic or other changes occurring in glandular epithelium during short- or long-term culture. Establishment of these changes is vital as a base line for the interpretation of cellular alterations in response to agents such as hormones or chemical carcinogens in vitro.

In this paper, we provide this base-line information by describing histologic changes in normal human prostate of young adults throughout long-term explant culture as long as 24 weeks, with emphasis on epithelial cells and their responses to in vitro conditions. Further, we compare responses in normal human prostatic epithelium with those of BPH.

MATERIALS AND METHODS

Tissues.—Human prostate tissues were obtained from 8 patients, 16-31 years old, during IA after accidental death (*13*) or surgically from 30 patients, 55-82 years old, treated for BPH by transurethral resection or suprapubic prostatectomy.

Explant culture.—Complete details pertaining to culture techniques used in this study are presented elsewhere (*14*). Explants were cultured in CMRL-1066 medium (Grand Island Biological Co., Grand Island, N.Y.) supplemented with antibiotics, 5% heat-inactivated fetal bovine serum, hydrocortisone, and insulin. Cultures were incubated at 37°C on rocker platforms (Bellco Glass, Inc., Vineland, N.J.) in an atmosphere of 5% CO_2, 45% O_2, and 50% N_2. Culture medium and gas phase were changed three times each week.

Fixation.—During intervals of culture, from zero time to 24 weeks, explants were sampled and fixed in mixed alde-

hydes (4% formaldehyde-1% glutaraldehyde in 200 mos*M* phosphate buffer) (*15*) and were processed for LM and histochemistry.

LM.—Fixed tissues were dehydrated through a series of graded alcohols, embedded in paraffin, cut at a thickness of 4-5 μm, and routinely stained with H & E.

Histochemistry.—For the study of mucosubstances, serial sections were stained with PAS with and without α-amylase digestion, AB-PAS sequence, AF-AB sequence, and mucicarmine. Before being stained with PAS, tissue sections were treated with dimedone (*16*), which blocked free aldehyde groups contributed by the glutaraldehyde component of the fixative groups that would otherwise react with the Schiff reagent producing a false-positive result.

RESULTS

Explants showed good preservation of morphology in culture for as long as 24 weeks for normal prostate and as long as 20 weeks for BPH, at which times all explants had been sampled. The observations described below are characteristic of all explants of normal prostate or BPH which showed survival of epithelial cells.

Zero Time Culture

Normal glands, IA.—By LM, normal prostate consisted of numerous tubuloalveolar glands and ducts surrounded by dense eosinophilic fibromuscular stroma (fig. 1). The glandular epithelium was composed of two cell types: *a*) columnar to cuboidal secretory cells with a foamy cytoplasm and large, round nuclei and *b*) flattened basal cells which lacked foamy cytoplasm and possessed a triangular or elongated, densely staining nucleus (fig. 2). Eosinophilic corpora amylacea were occasionally present in glandular lumina (fig. 1).

Histochemically, in dimedone-blocked histologic sections, PAS-positive, α-amylase-resistant granules were seen scattered within the cytoplasm of secretory epithelial cells (fig. 3). At the cell apex, the granules appeared coarser than elsewhere. Within gland lumina, these granules appeared free or in coarse aggregates, sometimes in association with PAS-positive amorphous material. PAS-positive granules and amorphous material were negative for acidic component by the AB-PAS or AF-AB sequence. In some acini, rather large PAS-positive, α-amylase-resistant droplets of varying diameter were present, especially in basal portions of secretory cells as well as within acinar lumina.

BPH.—LM of specimens of BPH showed varying degrees of glandular and stromal hyperplasia. The acini were sometimes enlarged with numerous papillary processes projecting into the lumina. Corpora amylacea were more frequently seen in BPH than in normal prostate. Otherwise, the histology and histochemistry were essentially identical to the histology and histochemistry of normal prostate, as described above.

One Week of Culture

Normal glands, IA.—Within explants during the first 2-3 days of culture, rapid degeneration and necrosis of secretory epithelial cells were striking features, although the rate of degeneration varied from acinus to acinus (figs. 4, 5). In some acini, an occasional pyknotic nucleus was seen; in other acini, large numbers of necrotic secretory cells sloughed into the lumen. Compared to acini near the surface of explants, degeneration appeared sooner and was more extensive in acini deep within explants. Eventually, within this time, some gland lumina were filled with heterogeneous eosinophilic cellular debris (figs. 5, 6). Some acinar cells did not degenerate but remained viable and appeared to repopulate acini and ducts denuded of secretory cells. Mitotic figures were sometimes seen among these cells during and subsequent to degeneration of secretory cells.

At the same time degenerative changes were occurring within the explants, epithelial cells migrated from exposed ducts or glandular spaces over the cut surfaces of explants. By 1 week of culture, the cut surface was shown by LM to be completely covered with a sheet of migrating cells, which was continuous with the cell sheet lining the exposed ducts or glandular spaces exposed to view after sectioning had been done. In occasional explants consisting only of stromal tissue, few migrating cells were seen.

Cells repopulating acini and cut surfaces of explants formed a multilayered epithelium characterized by widened intercellular spaces. The epithelium consisted of columnar to polygonal or flattened, squamous-like cells; polygonal cells predominated (fig. 6).

By histochemistry, the surface cells of the explant as well as the cells lining the glands within explants exhibited numerous PAS-positive, α-amylase-resistant granules, particularly in the apical portion above the nucleus (fig. 7). At the cell apex, granules were dense and intensely PAS-positive and were also frequently stained with AB (fig. 8) but not with AF; these staining patterns are consistent with both neutral and sialic acid-containing mucosubstances. In the supranuclear zone within these cells, granules usually stained only with PAS. AB-positive mucosubstances also stained with mucicarmine to varying degrees. The apical surfaces of cells appeared to stain with AB, AF, and mucicarmine. Substances with similar staining properties also were present within gland lumina.

BPH.—LM and histochemical observations for BPH were essentially identical to those described above for normal prostate. Squamous metaplasia was sometimes seen in specimens of BPH (fig. 9) but was not seen in normal prostate.

Two Weeks of Culture

Normal glands, IA.—Fewer tall columnar cells were seen at this time. An occasional mitotic figure was present among acinar and surface cells of explants. Few viable cells were noted in the fibromuscular stroma.

At this time, mucosubstances were abundant in cells with markedly convex apical surfaces. This observation was especially true for columnar cells, in which the convex apical surfaces persisted. Outer surfaces of cells continued to stain with AB, AF, and mucicarmine.

BPH.—Explant surfaces were covered by a mucus-secreting multilayered epithelium (fig. 10), essentially identical to that described above for normal prostate.

Three to Twenty-Four Weeks of Culture

Normal glands, IA.—Most cultures were terminated at 12–14 weeks. However, one experiment with normal prostate was terminated at 22 weeks and another was terminated at 24 weeks. Throughout this period, the surface sheet was maintained even in 24-week explants. It differed in thickness from area to area, yet the overall organization remained virtually the same (figs. 11, 12). Intact acini were lined by polygonal, cuboidal, or squamous-like cells and were generally limited to the peripheral zones of explants. Occasional mitotic figures were seen. During this interval, mucosubstances were present but in amounts that appeared diminished when compared to amounts during earlier intervals. There were fewer apical granules present in surface or acinar cells, yet histochemical staining was qualitatively similar to staining at earlier times. The surfaces of these cells continued to show an affinity for AB and mucicarmine. Few viable cells were present within the necrotic stroma.

BPH.—Morphologic and histochemical changes occurring in explants of BPH were identical to those changes described above for normal prostate. Squamous changes persisted in some BPH explants.

DISCUSSION

The present study is the first to describe LM of long-term explant culture of normal, nonhypertrophic, nonneoplastic human prostate obtained from young adult patients, with a comparison to BPH obtained from older individuals. Previous studies of cultured human prostate have usually used BPH from older men which had been obtained surgically because of obstructive prostatic disease (*4–10, 12*). Noyes (*11*) used prostate tissue from patients 50–70 years old, which was sampled at the time of cystectomy, and concluded that it was histologically "normal." However, BPH is a common entity beyond the age of 50 and is usually unnoticed until obstructive symptoms appear. Despite the similar response of BPH and normal prostate to in vitro conditions in the present paper, Franks (*1*) has concluded that BPH is *not* normal prostate. Moreover, there is a possibility of inadvertently sampling preneoplastic or neoplastic cells in older patients, which would invalidate studies on induction of malignant transformation by carcinogenic agents (*1*).

On the basis of continuity and similarities in morphology and histochemistry of cells colonizing explant surfaces and acinar structures throughout long-term culture of normal prostate and BPH, we conclude from the present work that epithelial cells covering explant surfaces are identical to and are derived from epithelial cells of acini. In these acini, cells in a basal location appeared to remain viable during degeneration and necrosis of secretory cells. The presence of occasional mitotic figures among these basally situated cells suggests proliferation followed by repopulation of acini and migration and colonization of explant surfaces. Thus it seems likely that proliferation of basal cells accounts for repopulation of acinar structures, colonization of explant surfaces, and synthesis and secretion of mucosubstances during early periods of culture.

Previous studies of BPH or normal prostate in explant culture have reported maintenance of viability of glandular epithelium for periods of typically less than 2 weeks to periods as long as 48 months (*4–9, 11, 12*). Usually, no distinction was made in these studies between columnar secretory cells and basal cells with regard to degeneration and necrosis nor were morphologic features described in detail, as we attempted in the present study. Maintenance of secretory epithelial cells with a columnar profile has been possible for as long as 10 days (*6*), although reduction in secretory vacuoles and cell height has been reported after only a few days in vitro (*4, 10*). Squamous changes have also been seen during early periods of culture (*4, 6, 9–11*). On the basis of the present study, it is very unlikely that epithelial cells seen during long-term explant culture of human prostate in previous work are viable columnar secretory cells. Rather, we propose that cultured prostatic epithelial cells seen by previous authors were derived from basal cells we have defined ultrastructurally (*17*).

The implication for a potential role of basal cells in the genesis of adenocarcinoma of the prostate is strongly suggested by the above observations and by morphologic evidence of premalignant and malignant changes in basal cell derivatives in response to *N*-methyl-*N'*-nitro-*N*-nitosoguanidine in vitro (*18, 19*). In this regard we also find it interesting that differentiated basal cells synthesize and secrete acidic mucosubstances during explant culture, which we report in the present paper. Although acidic mucosubstances are not demonstrable histochemically in the epithelium of normal prostate, they are frequently detected in prostatic adenocarcinoma (*20, 21*) and have staining affinities (neutral and acidic components) similar to those seen in the present study. Using histochemical techniques, Noyes (*11*) also detected neutral mucosubstances in the epithelium of prostatic explants after culture for 12 days, but he did not stain for acidic components, and thereby he failed to recognize synthesis and secretion of acidic mucosubstances in vitro.

Studies on Carcinogenesis of Human Prostate. III. Long-Term Explant Culture of Normal Prostate and Benign Prostatic Hyperplasia: Transmission and Scanning Electron Microscopy[1,2,3,4]

Barry M. Heatfield,[5] Hayato Sanefuji,[5,6] *and* Benjamin F. Trump[5,7,8]

ABSTRACT—Ultrastructural changes in normal human prostate and benign prostatic hyperplasia (BPH) during long-term explant culture were compared. Explants of normal prostate obtained at immediate autopsy of young adults or of BPH obtained at the time of surgery were maintained as long as 24 weeks in vitro. Ultrastructural changes occurring in epithelial cells during culture were monitored by transmission and scanning electron microscopy. Essentially identical results were found for normal prostate and BPH. During the first week of culture, secretory epithelial cells degenerated and sloughed into the acinar lumen, resulting in an accumulation of necrotic debris. During this period, however, epithelial cells with ultrastructural characteristics of basal cells remained viable, repopulated glandular structures, migrated from glands and ducts, and epithelialized adjacent cut surfaces, eventually covering the explant. On explant surfaces, these basal cells initially were squamous-like, but they later became typically cuboidal, polygonal, or sometimes columnar and formed an epithelium, two cells or more thick. Epithelium with similar features lined acini within explants. Epithelial cells at the surface or within explants were distinguished by the presence of microvilli, junctional complexes, multiple Golgi complexes, well-developed rough endoplasmic reticulum, polyribosomes, nuclei with prominent nucleoli, orthodox mitochondria, scattered tonofilaments, and a basal lamina. Some epithelial cells extended from the lumen to the basal lamina; others were oriented along the basal lamina and did not extend to the lumen. By 1–2 weeks in vitro, these epithelial cells began synthesis of mucus-like material. At later intervals of culture, microvilli were shortened and mucosubstances were reduced. During culture, the stroma became progressively hypocellular and necrotic. In summary, explant-cultured epithelial cells of normal human prostate or BPH were similar ultrastructurally and were found to originate from basal cells, which alone survive culture conditions.—JNCI 1982; 69:757–766.

Another paper in this series describes light microscopic and histochemical alterations in normal human prostate and BPH during long-term explant culture as long as 24 weeks (*1*). The results of this other study suggested that basal cells were responsible for epithelial recovery and growth in vitro (*1*). The present paper extends these observations to the ultrastructural level with the transmission and scanning electron microscopes and conclusively demonstrates survival and repopulation of glandular acini and colonization of explant surfaces of normal human prostate and BPH by epithelial cells having ultrastructural features identical to features of prostatic basal cells.

MATERIALS AND METHODS

Tissues.—Human prostate tissues were obtained from 8 patients, 16–31 years old, during IA after accidental death (*2*) or surgically from 30 patients, 55–82 years old, treated for BPH by transurethral resection or suprapubic prostatectomy.

Explant culture.—Complete details pertaining to explant culture techniques used in this phase of the study are presented elsewhere (*3*).

Fixation.—During intervals of culture, from zero time to 24 weeks, explants were sampled and fixed in 4% formaldehyde–1% glutaraldehyde in 200 mos*M* phosphate buffer (*4*).

Electron microscopy.—For TEM, fixed tissues were washed in three changes of 0.2 *M* cacodylate–7% sucrose buffer and postfixed in 1% OsO_4. Washed tissues were then stained en bloc with 1% uranyl acetate, dehydrated through a series of graded ethanols and propylene oxide, and embedded in Epon. For high-resolution LM, semithin sections were cut at a thickness of 1 µm and stained with toluidine blue (*5*); suitable areas were then selected for ultrathin sectioning. Ultrathin sections were stained with uranyl magnesium acetate and lead citrate and examined in a JEOL 100B electron microscope.

For SEM, fixed tissues were washed in three changes of 0.2 *M* sodium cacodylate–7% sucrose, postfixed in 2% OsO_4 for 1–2 hours, washed in 5–10 changes of 0.2 *M* sodium cacodylate–7% sucrose, and placed in saturated thiocarbo-

hydrazide (6) in distilled water for 20 minutes at room temperature. Specimens were then washed in 5-10 changes of distilled water, placed in OsO_4 for 30 minutes to 1 hour, dehydrated through graded ethanols, and subjected to critical-point drying (model E 3000; Polysciences, Inc., Warrington, Pa.) with liquid CO_2. Thereafter, dried specimens were mounted on aluminum stubs (E. J. Fjeld Co., Inc., Maynard, Mass.) with silver conductive paint (Acme Chemicals and Insulation Co., Division of Allied Products Corp., New Haven, Conn.), sputter-coated (Technics Inc., Alexandria, Va.) with gold-palladium for 5 minutes, and examined with an AMR-1000 scanning electron microscope.

RESULTS

Zero Time Culture

Normal glands, IA.—LM of Epon-embedded normal prostate at zero time revealed columnar to cuboidal secretory cells and nonsecretory basal cells lining glandular acini (fig. 1).

TEM of secretory cells showed a polarized distribution of cytoplasmic organelles. The most characteristic ultrastructural features of these cells were a well-developed Golgi complex and numerous vesicles and secretory vacuoles in the supranuclear zone (fig. 2). Secretory vacuoles possessed a variable number of heterogeneous inclusions including small, irregular dense bodies, small vesicles, and occasional membrane whorls. Short microvilli characterized the apical cell surface but were most numerous in narrow clefts between adjacent cells (fig. 2). Blebs on the apical surface were observed, and membrane-bound extracellular vesicles, vacuoles, and membrane-enclosed portions of the cytoplasm were often seen in contact with the outer surface of the apical plasma membrane, or they appeared free in the acinar lumen. The apical plasma membrane of some cells was disrupted or absent altogether. Lateral surfaces of adjacent cells were connected by tight junctions at the apex, with gap junctions and desmosomes present more basally between cells. Narrow intercellular spaces were crowded with interdigitating folds of the lateral plasma membrane. The basal portion of secretory cells, which abutted on the basal lamina, contained mitochondria, sparse RER, lipid droplets, free polyribosomes, and a few secretory vacuoles (figs. 2, 3). Above this portion were a few orthodox mitochondria and a round nucleus containing a single nucleolus. Lysosomes with a homogeneous, finely granular interior were scattered in all portions of the cell.

Nestled among the basal portions of columnar cells and in contact with the basal lamina were polymorphic basal cells that differed conspicuously from their secretory counterparts by the absence of secretory vacuoles and of a well-developed Golgi complex (figs. 2, 3). The nucleus was prominent in these cells, although other organelles were sparse (fig. 3). Numerous free polyribosomes were present, which contributed to an increased electron density of the cytoplasm. The basal lamina appeared as a thin, amorphous zone separating the underlying stroma from the epithelial layer (figs. 2, 3).

SEM of cut surfaces of explants showed glandular elements that were easily distinguished from stromal components. Glands were lined by epithelial cells. Epithelial cells covering folds or papillae of the gland wall projected into the acinar space in compact, grapelike masses (fig. 4). If tissues were fixed without additional trimming, glands exposed at cut surfaces were distorted and bulged outward. But when tissues were retrimmed after fixation and tissue contraction, a more normal histologic appearance of the gland was observed (fig. 4). The apical contour of epithelial cells was typically convex.

Short microvilli were distributed over the surface of each cell (fig. 5). In addition, the apical plasma membrane frequently was perforated by pores or holes (fig. 5); occasionally, the entire apical plasma membrane was absent. One interesting feature encountered to varying degrees in most glands was that of apical surface blebs. Blebs ranged from small, irregular or spherical protuberances (fig. 5) to smooth, balloon-like structures involving the entire apical plasma membrane.

BPH.—LM, TEM, and SEM of epithelial cells of BPH provided results similar to those obtained from normal glands, although morphologic integrity was not as satisfactory as it was in fresh glands obtained at immediate autopsy. In one case of BPH, lacunar separation of basal cells was observed, comparable to the separation seen during culture in vitro in normal glands and glands of BPH.

One Week of Culture

Normal glands, IA.—By 1 week of culture, most of the cut surfaces of explants of normal prostate were shown by LM to be covered by a sheet of cells continuous with the cell sheet lining ducts or glandular alveoli. Where bare areas were being covered, a single layer of flattened migratory cells was seen (fig. 6). Away from the leading edge of migrating cells, the sheet was 2-3 cells thick. Cells were either columnar (fig. 7), polygonal, cuboidal, or flattened and squamous-like. Cells were typically separated by widened intercellular spaces. In glands within the interior of explants, necrosis of columnar secretory cells was a common feature and was evident as early as 2-3 days of culture (fig. 8). The lumina were filled with cellular debris.

TEM of cells at explant surfaces showed a sheet of epithelial cells varying from one cell thick at the leading, migrating edge to 2-3 cells or more thick in more proximal locations resting on a basal lamina (fig. 9). Some cells extended from the basal lamina to the surface; others appeared intermediate in position or were flattened along the basal lamina. Typically, wide intercellular spaces separated cells (figs. 9, 10). Penetrating these spaces were microvillus-like projections, shown by SEM of exposed cell surfaces to be delicate folds of the plasma membrane (*see* fig. 14). These projections intermingled with or showed close apposition to those of neighboring cells. The outermost cells were connected to adjacent cells at the apex by tight junctions (fig. 10). Scattered along the apical surface were numerous microvilli. All cells comprising the surface sheet were attached at other points of contact by small desmosomes. Polarization of cell organelles was not conspicuous, with the exception of vacuoles as described below. Nuclei varied markedly in shape and were not restricted to basal regions of the cell. Typically, a single prominent nucleolus was present; condensed chromatin was scanty. Cells possessed multiple Golgi complexes, numerous, sometimes bizarre mitochondria, RER occasionally in whorl-like configurations, and free polyribosomes (figs. 9, 10). Other organelles present included lysosomes, occasional residual bodies, lipid droplets, microtubules, and small bands of filaments that resembled tonofilaments. In a few cells numerous myelin figures were seen. Characteristic inclusions, especially prominent in columnar cells, were membrane-bound vacuoles of variable size and number which were filled with flocculent material and frequently had a finely granular, moderately dense eccentric core. Vacuoles were closely associated with Golgi elements in some instances. The apical portion of some cells was packed with these vacuoles (fig. 10).

Deep within explants, normal prostate columnar secretory cells were seen in various stages of necrosis (fig. 11). Characteristic features of these secretory cells included numerous autophagic vacuoles, loss of organelles, disrupted cell membranes, and pyknotic nuclei. Basal cells remained viable (fig. 11), however, and lined lumina filled with cell debris. In some basal cells, numerous vacuoles were filled with dense heterogeneous material, lipid droplets, or myelin figures, suggesting heterophagy of secretory cell debris. Basal cells within explants also possessed mucus-filled vacuoles, sometimes in large numbers, and resembled or were identical to cells comprising the epithelium at explant surfaces. Microvilli varied in number.

SEM showed explant surfaces covered by tightly packed arrays of polygonal epithelial cells with flattened to convex surfaces on which numerous short microvilli were borne (figs. 12, 13), or it showed overlapping, squamous-like migratory cells with irregular surfaces and minute microvilli. When artifactual separation of surface epithelial cells occurred, petal-like lateral plasma membrane folds were revealed (fig. 14). Epithelial cells resembled normal glandular epithelium at zero time, except that microvilli were longer and covered the apical surface. Pores or holes in the apical plasma membrane were not seen. Surface blebs were uncommon. Occasionally, the cut surfaces of explants were naked; only a tangled, interlacing meshwork of collagen fibrils was seen. Encroaching on these bare areas were sheets of migratory cells, with characteristics of squamous-like epithelium.

BPH.—LM, TEM, and SEM observations of cultured BPH explants at this time were essentially identical to the observations described above for normal prostate. In some instances, degeneration of columnar secretory cells in acinar spaces within explants appeared earlier compared to normal glands.

Two Weeks of Culture

Normal glands, IA.—By LM, fewer tall columnar cells were observed at this time or at subsequent times; abundant necrotic debris was seen in acinar lumina within explants (fig. 15).

TEM revealed some reduction in height and numbers of microvilli and in apical vacuoles containing mucus-like material (fig. 16). Residual bodies, myelin figures, and lipid droplets were more numerous in epithelial cells lining acini than in those epithelial cells at the explant surfaces.

The outline and surface features of epithelial cells at the exterior of the explants were variable. Apical surfaces were polygonal and varied from flat to markedly convex, as seen by SEM (*see* fig. 18).

BPH.—Changes in cultures of BPH explants at this interval were essentially identical to the changes seen for normal glands.

Three to Twenty-Four Weeks of Culture

Normal glands, IA.—Intercellular spacing was more variable, yet the overall organization remained remarkably the same (fig. 17) when viewed by LM.

By TEM, small vacuoles enclosing mucus-like material occasionally were seen at 7 weeks' culture and were seen later, both in epithelial cells of explant surfaces and within explants. At 24 weeks, epithelial cells were similar to those at earlier times. Calcification of residual cell debris within some acini was noted.

By SEM, epithelial cells were polygonal with flattened to convex apical surfaces bearing shortened microvilli (fig. 18). In one specimen, both surface and underlying epithelial cells as well as collagen fibrils of subjacent stroma were visible. Small blebs of the apical plasma membrane were occasionally seen.

BPH.—BPH explants at 20 weeks were essentially identical in ultrastructure to explants described above for normal prostate. However, in 2 cases of BPH examined by SEM, some of the explants were covered with bizarre cells. Such cells piled up on explant surfaces, did not show close attachment to one another, but did appear loosely organized with cytoplasmic projections and filopodia contacting adjacent cells (fig. 19). There was little evidence of surface activity; only ripple-like undulations of the apical plasma membrane or tiny spherical projections were scattered over the cell surface. Cells with these features were not associated with explants derived from normal prostate.

With the exception of the bizarre alterations and occasional squamous metaplasia in BPH described above, no consistent differences were noted either in the pattern of in vitro epithelial response among the various normal prostates and cases of BPH studied or among explants of the same case of BPH in which basal cell types survived.

DISCUSSION

Before culture, the normal prostate of young adults and BPH in our study resembled BPH described in older patients (*7–16*). Two cell types were present: *a*) columnar to cuboidal secretory cells and *b*) nonsecretory basal cells. By SEM, a variety of apical surface features as well as several morphologic cell types have been described for secretory cells of BPH (*12, 13, 16, 17*) but have not been described for normal prostate. Stone et al. (*13, 16*) described *a*) microvillus cells possessing numerous microvilli (≥90% cells present), *b*) bare cells lacking membrane specializations, and *c*) ruffled cells characterized by the presence of variable numbers of tiny folds or microplicae. In addition, Clark et al. (*12*) observed numerous cells with pits or holes in the apical plasma membrane. In other cells, termed "crater cells," the entire apical portion of the plasma membrane was lost. Stone et al. (*13*, *16*) considered these features a preparative artifact, although they left open the possibility that crater cells represented active secretion. We observed microvilli on virtually all apical cell surfaces in samples of BPH and normal prostate; we did not observe naked or bare cells, and we rarely saw ruffled cells. Crater cells and cells with pits or holes were seen, however, and were especially prominent in areas of active secretion, where sometimes the entire apical cell surface formed a balloon-like bleb. Crater cells may arise by loss of this bleb during mechanical trauma and/or as a consequence of apocrine secretion. Cells with pits or holes may represent fusion of the secretory vacuole membrane with the plasma membrane, reflecting merocrine secretion. Both apocrine and merocrine secretory mechanisms appear to be operative in human prostate (*9*, *11*, *18*), which could account for these morphologic features. Similar disruptions of the plasma membrane were absent in cultured explants.

In contrast to secretory cells, basal cells are structurally undifferentiated (*7–11*, *19*). Little is presently known about the role of these cells in human prostate, although basal cells frequently are regarded as "reserve" cells (*7*, *9*, *11*, *18*, *19*), which implies a capacity to differentiate into secretory or transitional epithelial cell types when appropriately stimulated. In ultrastructural studies, possible transitional forms between secretory cells and basal cells have been noted (*11*, *13*). Experimental evidence also favoring this view was obtained by Dermer (*19*) who studied [^{3}H]thymidine incorporation by epithelial cells of BPH in vitro by the use of autoradiographic techniques. He observed nuclear labeling (0.1%) associated only with cells in a basal location and concluded that basal cells are capable of proliferating and may be a source of secretory cells. Our in vitro studies (*20*) of normal human prostate also have demonstrated the capacity of basal cells to divide. The factor(s) stimulating proliferation of these cells is not yet known, although death of secretory epithelial cells within a given acinus during early culture appeared to be correlated with incorporation of [^{3}H]thymidine by basal cells as determined by autoradiography. That basal cells are capable of differentiation is supported by our in vitro studies (*1*), which demonstrated mucus metaplasia in cells repopulating glands and ducts and colonizing explant surfaces. In ultrastructure, the contents of these secretory vacuoles, as described above, resembled mucus-like material. Moreover, the distribution of these vacuoles within basal cells during culture corresponds to the pattern of histochemical staining for acidic mucosubstances, as demonstrated elsewhere (*1*).

Similarity in morphology, histochemistry, and continuity of epithelia revealed by LM (*1*) together with similarities in ultrastructure described in the present paper leave little doubt that epithelial cells colonizing acini and exterior surfaces of explants and differentiating in vitro are derived from prostatic basal cells. In previous studies, Schrodt and Foreman (*21*) using TEM examined explants of BPH in short-term experiments up to 9 days in vitro. They also noted the early presence of degenerating secretory epithelial cells lining a few acini and the subsequent appearance of squamous-like epithelial cells with prominent tonofilaments, which appeared to represent altered basal cells.

Other evidence also supports the origin of cultured prostatic epithelial cells from basal cells. For example, Franks et al. (*22*) examined the role of stroma in maintenance of growth capacity of BPH in vitro. During mechanical separation of glandular epithelium from the underlying stroma, mechanical forces resulted in the apparent shearing and destruction of myoepithelial (basal) cells, as judged by adherence of nuclei of ruptured cells to the overlying secretory cells seen by TEM. Such preparations did not survive in vitro, nor did they incorporate [^{3}H]thymidine, although epithelium (probably basal cell derivatives) of intact explants could be maintained for many months in vitro. In view of the capacity of basal cells but not of secretory cells to proliferate, it is probable that destruction of basal cells was responsible for the subsequent lack of growth of mechanically separated epithelia. In related studies, Stone et al. (*23*) isolated glandular structures from BPH by enzymatic separation of epithelium and stroma. Glandular isolates were then cultured for 7 days in vitro and examined by SEM. The surface morphology of these isolates was very similar to that of explants illustrated in this paper, including the presence of features such as microvilli and convex apical surfaces.

The results of our in vitro studies so far have focused attention on prostatic basal cells, which may play an important role in neoplasia of the human prostate. The possibility that basal cells are important in the pathogenesis of BPH and prostatic carcinoma has been given little attention in the past. However, in recent in vitro studies we have demonstrated morphologic evidence of malignant transformation of basal cells of normal human prostate in response to chemical carcinogens (*24*, *25*), which strongly suggests an important role for these cells in the pathogenesis of prostatic adenocarcinoma.

In contrast to explant-cultured epithelial cells of normal prostate, bizarre cells seen on explant surfaces from 2 cases of BPH after 8 weeks' culture in the present study closely resemble epithelial cells associated with long-term cultured explants of prostate adenocarcinoma and carcinogen-exposed explants of normal prostate (*24*, *25*). The fact that similar cells were not seen on explants of normal prostate supports the contention by Franks (*26*) that BPH cannot be considered normal prostate. Thus BPH may be of limited usefulness in experimental studies in which responses of normal prostate are required, despite ultrastructural and histochemical (*1*) similarities between normal prostate and BPH in vivo and in vitro.

In conclusion, our studies have identified basal cells as those cells responsible for new epithelial growth of normal prostate and BPH in vitro. By use of an in vitro approach, secretory cell types can be eliminated, enabling further comparative studies on the characteristics of basal cells in normal and pathologic human prostate.

Enhancement of Growth of Human Colon Tumor Cell Lines by Feeder Layers of Murine Fibroblasts[1,2]

M. G. Brattain,[3,4,5] D. E. Brattain,[3] A. M. Sarrif,[5,6,7] L. J. McRae,[5] W. D. Fine,[3] *and* **J. G. Hawkins[3]**

ABSTRACT—The effects of feeder layers of C3H/10T½ cells on the growth of human and mouse cell lines were tested. Feeder layers increased colony formation by cultured cancerous cells in semisolid medium over controls grown in semisolid medium without feeder layers. Maximal colony formation was also attained at a faster rate when feeder layers were used. Plating efficiency by cancerous cells obtained directly from xenografts was increased threefold to fivefold in tissue culture when feeder cells were present as confluent monolayers.—JNCI 1982; 69:767–771.

Although some advances have been made with certain types of cancers in recent years, the cure rates for colon carcinoma have remained largely unchanged over the past two decades (*1*). This is in part due to the lack of effective chemotherapeutic agents against this disease (*2*). In vitro models would be helpful for the development of chemotherapeutic agents, but there has been little success with regard to the elucidation of routine methods for the tissue culture of colon carcinoma (*3–5*). Recently, however, we described the utilization of feeder layers of C3H/10T½ cells for the improved establishment of human colon tumors in tissue culture (*6*). Several studies have described the establishment of tissue cultures of human tumors with the use of a variety of normal cells and tissues as feeder layers for the cancerous cells (*7–12*).

The effects of C3H/10T½ cells on the growth of human colon carcinoma have not been widely studied. Therefore, we have attempted to evaluate the potential for the application of feeder layers to the tissue culture of human colon carcinoma *a*) by determining the effects of normal mouse embryo fibroblasts on the growth of established cell lines of colon carcinoma in soft agar and *b*) from xenografts. Both of these modes of culture are of potential importance in the development of suitable systems for prediction of the chemotherapeutic effects of drugs (*11*, *13*).

MATERIALS AND METHODS

Cell lines.—The cell lines utilized in this study were developed from primary human colon tumors in this laboratory and are described elsewhere (*6*, *14*). All five lines formed tumors in nude mice, grew in semisolid medium, and produced moderate (HCT 116, HCT 214) to large (HCT 525, HCT 116a) amounts of CEA in tissue culture, except for line HCT 116b, which produced low amounts of CEA. All cell lines were maintained at 37°C in an atmosphere of 5% CO_2, with McCoy's 5-A medium supplemented with 10% heat-inactivated FBS and antibiotics (4.3 µg gentamicin/ml, 90 µg streptomycin/ml, and 90 U penicillin/ml). Cultures were routinely subcultured weekly with 0.25% trypsin–0.1% EDTA in tissue culture medium. C3H/10T½ cells were maintained under the same conditions as the human cell lines. Benzo[*a*]pyrene-transformed cells (type III) derived from C3H/10T½ cells were also maintained under the same conditions. The properties of these cells and the C3H/10T½ cells have been described in detail in (*15*, *16*). Human breast cancer cells (734B) were obtained from the Naval Bioscience Laboratory, Oakland, Calif., and human melanoma cells (designated M-21) were obtained from Dr. Charles Balch, University of Alabama, Birmingham, Ala.

Culture in semisolid medium.—Soft-agarose culture of human colon carcinoma cells was performed as described previously (*14*, *17*). Other cell lines were grown by the standard soft-agar technique described by Salmon and co-workers (*13*) without feeder layers of spleen cells. In this system underlayer ingredients contained 40 ml enriched McCoy's 5-A medium, 10 ml tryptic soy broth (3%), 0.6 ml L-asparagine (6.6 mg/ml), and 0.3 ml DEAE-dextran. Enriched McCoy's 5-A medium (500 ml) contained 5% horse serum, 10% FBS, 5 ml sodium pyruvate (2.2%), 1 ml L-serine (21 mg/ml), and 5 ml (200 m*M*) glutamine. Underlayers were plated by mixing this medium with 3% agar to give a final concentration of 0.5% agar. Cells were plated into an upper layer of 0.3% agar which contained in 100 ml of CMRL-1066 medium: 15% horse serum, 4 ml (100 m*M*) $CaCl_2$, 200 U insulin, 1 ml (30 m*M*) vitamin C, and 2 ml (200 m*M*) glutamine.

In experiments testing the effects of feeder layers, 5×10^4 C3H/10T½ cells were plated into 9.6-cm^2 tissue dishes and permitted to grow to confluence in approximately 3 days. Underlayers (1 ml) of 1% agarose in McCoy's 5-A medium with 5% FBS were plated directly onto the confluent C3H/10T½ cells and incubated at 37°C in 5% CO_2 for 48 hours. Cells (5×10^4) from the colon carcinoma cells described above were suspended in growth medium containing 0.5% agarose B in McCoy's 5-A medium with 1 ml 5% FBS at

39°C and plated onto the underlayer containing 1% agarose B. This upper layer was then permitted to solidify at room temperature for approximately 30 minutes and subsequently maintained at 37°C in an atmosphere of 5% CO_2. Other cell lines were treated in the same manner except that the Salmon system (*13*) of soft-agar culture was utilized and the number of cells inoculated was varied. Control dishes were prepared in exactly the same manner except that there were no feeder layers of C3H/10T½ cells. Some cultures were fixed in glutaraldehyde immediately after solidification of the upper layer and stored at 4°C as time 0 samples (T_0) for comparison with experimental cultures at various times (1, 2, and 3 wk after plating). Each experiment was performed with a T_0 flask and three cultures for each week. Colonies of 20 cells or more were scored microscopically.

Xenograft tissue culture.—Cells from the human colon carcinoma cell lines were removed from 75-cm^2 tissue culture flasks with the trypsin-EDTA mixture described above, harvested by centrifugation at 98×*g* for 7.5 minutes, and resuspended in tissue culture medium, and 10×10^6 cells were injected sc into BALB/c athymic nude mice bred in our own laboratory. Xenografts were allowed to grow to a diameter of approximately 2 cm. The animals were then killed, and the tumors were removed by a sterile technique and placed into sterile tissue culture medium. Tumors were prepared for tissue culture as previously described (*6*, *14*). Tumors were minced to 1- to 2-mm^3 pieces, washed extensively in tissue culture medium containing 10% FBS, and subsequently disaggregated to single cell suspensions with 0.25% trypsin. Cell suspensions were harvested by centrifugation at 98×*g*, resuspended in the standard growth medium described above, and inoculated (5×10^4) into 25-cm^2 tissue culture flasks. Cells from each tumor were inoculated into six flasks, three of which contained confluent monolayers of C3H/10T½ cells. Each experiment consisted of three xenografts of each cell line. After 72 hours the entire volume of medium was changed, and colonies (≥20 cells) were scored microscopically. Colonies were scored again 6 days after plating.

RESULTS

Growth in Semisolid Medium

All five of the colon tumor cell lines formed colonies in soft agarose without feeder layers except HCT 525. Maximal colony formation was observed at 2 or 3 weeks, after which the colonies began to deteriorate through extensive disintegration of the cells. HCT 525 cells grew very poorly in soft agarose and HCT 116 and HCT 116b showed moderate colony formation relative to the other lines, whereas HCT 214 and HCT 116a grew relatively well in soft agarose without feeder layers (table 1). The addition of feeder layers to the soft-agarose system had dramatic effects on the extent of colony formation. Increases in colony formation were in the range of fivefold to ninefold for those lines that had moderate or low colony formation without feeder layers, whereas HCT 214 and HCT 116a showed an approximately twofold increase. The presence of feeder layers in the soft-agarose system also had the effect of speeding up the growth rate of the cell lines. Maximal colony formation was twofold to fourfold higher than colony formation after the first week for all of the cell lines, except HCT 525, when feeder layers were not included in this system. When feeder layers were added to the soft-agarose system, there were no significant changes in colony formation after the first week, except for HCT 116a, which showed an approximately twofold increase after 3 weeks of culture. Stimulation of proliferation of colon carcinoma cells was also demonstrated in tissue culture with conditioned medium from confluent C3H/10T½ cells grown in McCoy's 5-A medium enriched with 10% FBS (table 1). Although stimulation was observed with conditioned medium, it was generally lower than that obtained with feeder layers in the agarose system that was supplemented with 5% FBS. Reduced stimulation may have been due to the presence of 10% FBS required for optimal growth by C3H/10T½ cells in conditioned medium or possibly due to lower concentrations of conditioning factors in conditioned medium. Conditioned medium was harvested after 16-hour contact with confluent C3H/10T½ cells, whereas feeder layers were continuously present during the period of agarose culture.

The preliminary results obtained with human colon carcinoma cells raised the questions as to whether stimulation could be achieved with a more enriched medium such as the soft-agar culture system described by Salmon and coworkers (*13*), whether other types of malignant cells could be stimulated by C3H/10T½ cells, and whether the concentration of cells plated affected the obtained results. To answer these questions, we cultured different types of malignant cells at concentrations ranging from 10^3 to 5×10^3 cells in the soft-agar culture system described by Salmon et al. (*13*). The cell lines selected for this study included the HCT 116 human colon carcinoma, benzo[*a*]pyrene-transformed C3H/10T½ cells (type III), the M-21 human melanoma cell line, and the 734B human breast carcinoma cell line. All four of these cell lines were stimulated by feeder layers of C3H/10T½ cells as described below.

Cloning efficiencies for HCT 116 were considerably higher in the soft-agar culture system of Salmon et al. (*13*) than in soft agarose containing McCoy's 5-A medium enriched with 5% FBS (text-fig. 1). In addition, we observed

TABLE 1.—*Effects of C3H/10T½ cells on growth of human colon carcinoma cells in soft agarose and in tissue culture*

Cell line	Cloning efficiencies, %[a] (range)		Cloning efficiencies,[b] ratio (range): With conditioned C3H/10T½ medium
	Without feeder layer	With feeder layer	
HCT 214	1.5 (1.2-1.8)	2.9 (2.4–3.4)	2.2 (2.1–2.3)
HCT 525	0	1.1 (0.8–1.3)	3.0 (2.6–3.7)
HCT 116a	2.2 (1.9–2.8)	4.3 (3.8–5.1)	1.9 (1.6–2.5)
HCT 116	0.8 (0.7–1.1)	4.4 (3.7–4.8)	1.3 (1.1–1.4)
HCT 116b	0.5 (0.4–0.7)	3.7 (3.3–4.8)	1.9 (1.5–2.6)

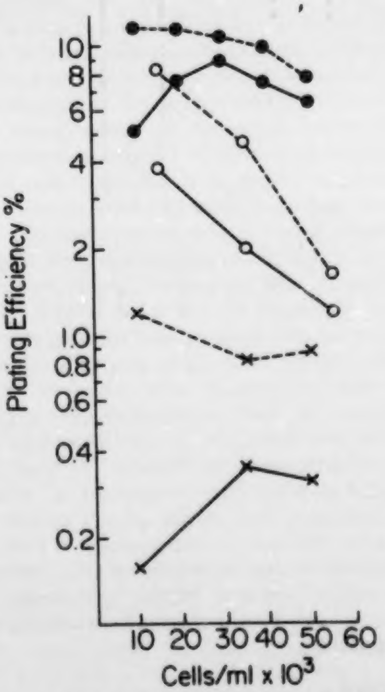
[a] Cloning efficiencies are expressed as the percent of cells plated giving rise to colonies. The entire dish was scored for colonies. Values represent the average of three separate expts.

[b] Results are expressed as the ratio of the No. of cells grown in the presence of conditioned C3H/10T½ cell medium in 25-cm^2 flasks to the No. of cells obtained from control flasks as described in the "Materials and Methods" section. Values are the averages of ratios obtained from three expts comprising duplicate experimental and control flasks.

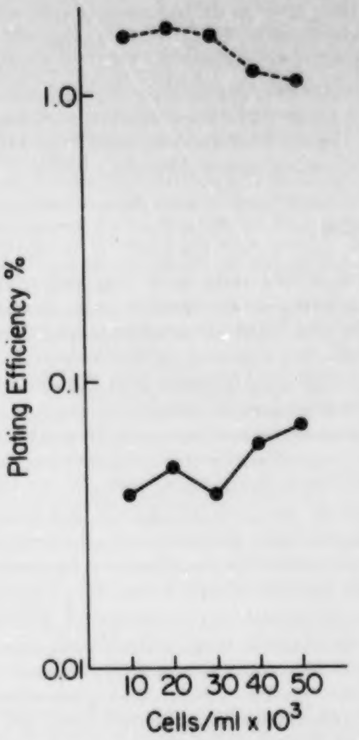
that the efficiency of colony formation was dependent on cell concentration, and maximal efficiency occurred in the range of 3×10^3 cells plated. We observed stimulation of colony formation by feeder layers of C3H/10T½ cells at all cell concentrations tested, but the extent of this stimulation was less than that obtained from the soft-agarose culture experiments described in table 1. Stimulation of colony formation was more pronounced at lower than at higher cell concentrations.

Colony formation by chemically transformed C3H/10T½ cells was stimulated by more than twofold at low cell concentrations with feeder layers of C3H/10T½ cells, whereas at higher cell concentrations the degree of stimulation was considerably reduced (text-fig. 1). We obtained similar results with the human melanoma cell line, except that stimulation was approximately tenfold at culture inocula of 10^3 cells and threefold at higher cell concentrations (text-fig. 1). Particularly striking was the stimulation observed with the mammary carcinoma cell line (text-fig. 2). Control cultures gave rise to only 5–40 colonies per plate over the range of 10^3–5×10^3 cells plated, whereas cultures with C3H/10T½ feeder layers were stimulated by approximately 25-fold at low inocula and 15-fold at higher inocula.

Several of the cell lines were not stimulated by C3H/10T½ cells in the soft-agar assay system. These included the previously described mouse colon carcinomas CT26 and CT51 (*17*), two human colon carcinoma cell lines, and untransformed C3H/10T½ cells.



TEXT-FIGURE 1.—Effects of cell inocula on colony formation: -----, in the presence of feeder layers; ——, in the absence of feeder layers. ●, HCT 116 cells; ○, chemically transformed C3H/10T½ cells; ×, M-21 melanoma cells. Cultures were plated according to the soft-agar system described by Salmon et al. (*13*).



TEXT-FIGURE 2.—Effect of cell inoculum on colony formation by 734B cells: -----, in the presence of feeder layers; ——, in the absence of feeder layers. Cultures were plated according to the soft-agar system described by Salmon et al. (*13*).

TABLE 2.—*Enhancement of colony formation by cancerous cells obtained directly from xenografts on feeder layers of C3H/10T½ cells*

Cell line	Time, days	Total No. of colonies[a] (range)	
		Without feeder layer	With feeder layer
HCT 214	3	0.7 (0.5–0.8)	2.0 (1.5–2.9)
	6	1.0 (0.9–1.1)	4.1 (3.0–4.7)
HCT 525	3	0.2 (0.2–0.3)	0.3 (0.2–0.3)
	6	0.9 (0.7–1.3)	1.3 (1.2–1.5)
HCT 116a	3	0.4 (0.4–0.5)	1.8 (1.5–2.2)
	6	1.2 (0.9–1.4)	5.5 (5.1–6.1)
HCT 116	3	0.6 (0.4–0.7)	1.7 (1.1–2.1)
	6	0.9 (0.8–1.0)	3.5 (3.3–3.9)

[a] Colony formation is expressed as total No. of colonies per 25-cm² tissue culture flask. The entire flask was scored for colonies. Values represent the averages of duplicate flasks for three different xenografts of each cell line.

Effects of Feeder Layers on Colony Formation by Xenografts

All of the cell lines except HCT 116b grew as discrete epithelioid colonies when plated onto plastic or confluent monolayers of fibroblasts. Clear demarcation of the colonies permitted determination of plating efficiencies of cell suspensions obtained directly from xenografts (table 2). HCT 116b cells would form clear-cut colonies on confluent fibroblasts, but they grew as diffuse areas of cells when plated on plastic. Consequently, HCT 116b xenografts were not included in this study. Except for HCT 525, plating efficiencies were increased threefold to fivefold when cells from xenografts were plated onto confluent monolayers of C3H/10T½ cells. Colony formation by cells from HCT 525 xenografts was increased approximately 1.5-fold.

DISCUSSION

The results of this study show that feeder layers of C3H/10T½ cells enhance colony formation by human colon carcinoma cells both from tissue culture and from xenografts resulting from the injection of the cultured cells in nude mice. Other types of malignant cells can also be stimulated. Recently, we described improved initiation of human colon tumor cell lines on feeder layers of C3H/10T½ cells (*6*). The mechanism responsible for this enhancement is unknown at present, but likely possibilities include the production of "growth factors" by C3H/10T½ cells and/or increased attachment of cancerous cells due to their interaction with the fibroblasts. The stimulation of colony formation by feeder layers in soft-agarose culture and the enhancement of cell proliferation on plastic by conditioned medium strongly suggest the production of growth factors, since the feeder layer cells and the cultured cancerous cells are not in direct contact in this system. Moses and co-workers (*18*) have shown that chemically transformed C3H/10T½ cells produce a growth factor that can induce normal fibroblasts to form colonies in semisolid medium. Gallie and co-workers (*12*) have described the growth of human retinoblastoma cells with the use of C3H/10T½ cells, as well as other types of fibroblasts. These investigators found that the cancerous cells required direct contact with the fibroblasts, suggesting that "conditioning factors" for these cells may be particularly labile. Other types of fibroblasts have been found to stimulate clonal proliferation of biopsy specimens of human colon carcinoma in soft-agarose culture (*19*).

Both the growth rate and the extent of growth appear to be increased when feeder layers of C3H/10T½ cells are utilized in the soft-agarose system for human colon carcinoma. Maximal growth in semisolid medium with feeder layers is generally achieved within 1 week of inoculation. Without feeder layers, 2-3 weeks are required for a maximal level of growth, which is considerably lower than that obtained with the feeder layers. Apparently, there are many cells with the potential to form colonies in soft agarose, which for unknown reasons do not grow. The addition of feeder layers to the system enables a higher proportion of these cells to grow. However, it is not clear whether the fraction of cells that grow in soft agarose in the presence of feeder layers represents the total number of cells with the potential to form colonies and whether growth is limited by the availability of nutrients, for instance. The size of the colonies when maximal growth has been attained is not significantly different for cultures with or without feeder layers.

Recent studies described the biologic heterogeneity of malignant cell populations comprising individual tumors (*20-24*), including human colon carcinoma (*14*, *25*). The concept of heterogeneity suggests the possibility that the additional growth observed in the presence of feeder layers may represent colony formation by different cells from those that grow in the absence of feeder layers. This concept is of paramount importance to the development of in vitro assays for drug screening because those cells that do not grow in the absence of feeder layers may have significantly different drug sensitivities from those that form colonies under these conditions.

Colony formation by cancerous cells from xenografts was considerably higher than that obtained for soft-agarose culture. It is impossible to estimate the effects of the production of growth factors by feeder layer cells in this system, since cancerous cells were in direct contact with the monolayers of C3H/10T½ cells. Higher plating efficiencies with feeder layers may have been promoted by adhesive interactions between the two cell types. In general, after 6 days, colonies on feeder layers were approximately twice the surface area of colonies that resulted from plating of xenograft cells directly onto plastic. However, it is impossible to determine whether these larger colonies represented more cell growth, since it is not clear whether the surface area occupied by a cancerous cell growing on top of a fibroblastic monolayer is the same as that of a cell growing on plastic.

Another area of potential applicability of feeder layers is in the development of in vitro assay systems for drug sensitivity screening. As indicated above, this is particularly important with regard to colon cancer because of the general lack of effective chemotherapy for this disease. Currently, clonogenic assay methods have not been effective for colon carcinomas disaggregated by mechanical means (*26*). Some cluster formation from enzymatically digested tumors has been observed for solid colon carcinoma, but a suitable assay for drug sensitivity screening has yet to be developed (*27*). The enhancement of growth by feeder layers may allow sufficient colony formation of a higher percentage of specimens for drug screening in a soft-agar assay system. Recently, Smith and co-workers (*11*) have described the utilization of feeder layers in the development of a clonogenic assay system in which second-passage cells from cultured mammary carcinomas are plated directly onto fibroblasts. The number of colonies formed is linear with respect to the concentration of cells seeded, and plating efficiencies are considerably higher than those generally obtained with clonogenic assays of primary solid tumors in soft-agar culture. Consequently, these investigators have suggested that assays that involve direct plating onto fibroblasts might find application in drug-sensitivity testing (*11*). Our results with cells obtained directly from xenografts of human colon carcinoma indicated that clonal growth directly on fibroblasts is easily obtained in this system. We are currently investigating the comparative plating efficiencies of malignant colon cells in soft-agar systems with feeder layer cells and in systems with direct contact between the malignant cells and fibroblasts.

Major Histologic Types of Cancers of the Gum and Mouth, Esophagus, Larynx, and Lung by Sex and by Income Level[1,2]

V. L. Ernster,[3,4] S. Selvin,[5] S. T. Sacks,[3] D. W. Merrill,[6] *and* **E. A. Holly[3,7]**

ABSTRACT—Incidence rates by income level were computed for squamous cell carcinomas of the gum and mouth, larynx, and esophagus and for squamous cell carcinoma, small cell carcinoma, and adenocarcinoma of the lung in white males and females aged 35–64 years, with the use of data for the nine geographic areas of the Third National Cancer Survey and the 1970 U.S. census. Within sex, age, and geographic area groups, patterns of cancer incidence by income level were analyzed by use of a nonparametric statistical method. Higher rates for males than for females were found for every histologic type studied, and the ratio of male-to-female rates increased with age (especially for squamous cell carcinomas of the larynx and lung). A strong inverse relation to income level was found for all of the histologic types studied in males and for squamous cell carcinomas of the gum and mouth and esophagus and small cell carcinoma of the lung in females. These findings are discussed with reference to patterns of smoking and alcohol use by sex and social class.—JNCI 1982; 69:773–776.

Epidemiologists have long been interested in the differential distribution of disease patterns across social groups. Such patterns can suggest life-style or other associated characteristics more directly implicated in disease etiology. The relation of sex and socioeconomic status to cancer rates has therefore been examined by numerous previous investigators, although few studies have considered rates by histologic type of cancer studied. Using data from the TNCS, conducted in the United States during 1969–71, we report incidence rates by sex, age, and income level for major histologic types of the following four cancer sites: gum and mouth, larynx, esophagus, and lung. We have selected these four sites because studies using TNCS data are under way elsewhere (*1*) on the relation between socioeconomic status and cancers of other major sites and because the four sites are all strongly associated with tobacco use.

MATERIALS AND METHODS

Incidence rates by age were computed for white males and females aged 35–64 for major histologic types of cancers of the gum and mouth, esophagus, larynx, and lung. Cancer incidence data were drawn from the population-based TNCS, conducted in nine areas (population of 21 million) of the United States during 1969–71 (*2*). Denominator data for the populations at risk by sex and age for the nine survey areas came from the 1970 tapes of the U.S. Bureau of the Census. The histologic types selected include squamous cell carcinomas of the gum and mouth, larynx, and esophagus and squamous cell carcinoma, small cell carcinoma, and adenocarcinoma of the lung.

Each cancer patient was assigned to one of three income levels based on the median income of his or her census tract of residence. For each of the nine TNCS areas, income was divided into thirds using median income for each census tract within that area. When the data were analyzed across areas, an individual (and his or her census tract population at risk) remained in the same tertile, even though the precise dollar cut points of the income tertiles varied from area to area. This approach assumes that relative income distributions are similar across areas.

A nonparametric method was used to analyze the association between cancer incidence (by site and histologic type) and the three income levels and is described in "Appendix." The significance probabilities used in the presentation reflect the likelihood that observed associations occurred by chance. Of course, these *P*-values indicate the impact of random variation on a single comparison and only generally reflect the overall likelihood associated with the large number of ad hoc comparisons made within this data set.

RESULTS

Table 1 shows for white males and females the number and proportion that each histologic type under study comprised of all microscopically confirmed cancers of the gum and mouth, esophagus, larynx, and lung. For every histologic type studied, the proportion with microscopic confirmation was at least 98% in the overall TNCS data set (*2*).

We first examined incidence rates by sex and age for each of the histologic types of cancer studied (table 2). Rates for males were higher than those for females in every case, and the ratio of male-to-female rates increased with age. The relative excess in male rates at older ages was particularly marked for squamous cell carcinomas of the larynx and

lung, with male-to-female ratios at ages 55–64 of 7.4 and 7.1, respectively.

Among males we found a strong inverse relation to income level for all of the histologic types of cancer studied (table 3). Among females we found an inverse association for squamous cell carcinomas of the gum and mouth and esophagus and for small cell carcinoma of the lung. A similar relation was seen for squamous cell carcinoma of the larynx, but this finding is of borderline significance. There was no association with income for squamous cell carcinoma

TABLE 1.—*Proportion of cases each histologic type examined comprised of the cancers studied, TNCS, 1969–71*[a]

Site and type of cancer	White males		White Females	
	No.	Percent	No.	Percent
Gum and mouth, all histologic types	925	100.0	538	100.0
Squamous cell carcinoma	843	91.1	450	83.6
Larynx, all histologic types	1,921	100.0	258	100.0
Squamous cell carcinoma	1,825	95.0	251	97.3
Esophagus, all histologic types	967	100.0	351	100.0
Squamous cell carcinoma	723	74.8	296	84.3
Lung, all histologic types	14,199	100.0	3,695	100.0
Squamous cell carcinoma	5,352	37.7	781	21.1
Small cell carcinoma	1,979	13.9	540	14.6
Adenocarcinoma[b]	2,437	17.2	1,187	32.1

[a] Values are based on microscopically confirmed cases and represent all age groups combined, not just those groups aged 35–64 examined elsewhere in this report.

[b] This category includes alveolar adenocarcinoma, papillary adenocarcinoma, mucin-producing adenocarcinoma, acinar cell carcinoma, adenosquamous carcinoma, and adenocarcinoma, not otherwise specified.

of the lung or adenocarcinoma of the lung in females (table 4).

DISCUSSION

Our findings show that the inverse relation between income level and selected cancer sites reported in the past continues to be seen in relatively recent population-based incidence data.

Squamous cell carcinoma comprises the vast majority of cancers of the gum and mouth, larynx, and esophagus in both men and women. Thus it is not surprising that the male excess in rates and the inverse relation to social class found here replicate the work of previous investigators who have considered all histologic types of those cancers combined (*3–8*). Published reports on incidence of those cancers by social class among women are fewer and show either an inverse relation (*8, 9*) or no clear gradient (*4, 5*). Smoking has traditionally been more common in men than in women, and the association between smoking and cancers of those sites is well established (*10*). The lower male-to-female rate ratios at younger ages compared to older ages are consistent with a narrowing of smoking differences between the sexes over time, a pattern that has been documented in national smoking surveys (*10*). Alcohol use is also clearly associated with increased risks of cancers of the oral cavity, larynx, and esophagus (*10*), and rates of heavy alcohol use are much higher in men than in women in the United States (*11*). The proportion of drinkers is higher among younger than older women, although the percentage of heavy drinkers is relatively constant across age groups (*11, 12*).

The literature on smoking and drinking patterns by social class is replete with inconsistencies, and only a few of the many relevant published studies can be cited. Among men, smoking has been more common in those with relatively low levels of education and occupational status (*10*) and was also inversely related to a four-component (education, occupation, income, and rent) socioeconomic index (*13*); however, no consistent relation to income alone has been shown in national surveys (*14*). The measure of social class used here, i.e., median income of census tract of residence, may not reflect individual income as much as a more broadly defined "social environment."

Alcohol use and heavy drinking have been positively related to social class in men in some reports (*11*), which is inconsistent with the inverse income gradient that we found for cancers of the gum and mouth, larynx, and esophagus. Others (*15, 16*) have reported an inverse association between alcohol use and social class, consistent with the cancer rates reported here. One of these studies, based on a subset of the TNCS data, found cigarette smoking and alcohol use to be highly correlated with one another (*16*).

In women there has been no clear-cut association between smoking patterns and education or occupation (*10*), but there was an association with the four-component socioeconomic index (*13*) and with income (*14*). Williams and Horm (*16*) reported a strong positive relation between alcohol consumption and both education and family income in women. It is difficult, therefore, to explain the inverse association we found between income level and cancers of the gum and mouth, larynx, and esophagus in women on the basis of smoking and alcohol consumption alone.

The relative frequencies of the major histologic types of lung cancer differ between males and females. In the TNCS data, squamous cell carcinoma comprised 38% of all microscopically confirmed cases of lung cancer in men and only 21% in women, whereas small cell carcinoma comprised nearly equal proportions in the two sexes (13.9% in men and 14.6% in women) and adenocarcinoma accounted for 17% of lung cancer in men and 32% in women. We found a marked male excess in squamous cell carcinoma rates, particularly in males at the older ages, which again reflects a reduction in smoking differences between men and women over time. The strong reverse gradient between income level and both squamous cell carcinoma and adenocarcinoma in men but not in women may be due to the inverse association between smoking and social class noted for men only. However, it is then curious that small cell carcinoma of the lung is inversely related to social class in women as well as in men. Such inconsistencies suggest that some histologic types have etiologies different from others and point to the need for further investigations by histologic type.

In this regard, it has been suggested that the relation of cigarette smoking to lung carcer is stronger for squamous cell carcinoma than for other histologic types, a notion that some investigators have confirmed and others have refuted (*10*). Of interest are the preliminary results of a case–control study among Chinese women in Hong Kong; adenocarcinoma and large cell carcinomas comprised 79% of tumors among the 111 female patients studied, and more than half of these patients were nonsmokers (*17*).

The lack of consistency across studies in the United States that address the relationship between smoking, alcohol consumption, and socioeconomic status suggests that there are factors related to social class, not limited to smoking and drinking, that differentially influence rates for histologic types of the cancers we examined. Of course, it is important to take into account variations by social class in type and amount of cigarettes and alcohol consumed, patterns of smoking in relation to drinking practices, and time trends in such behaviors, which have not been explored here.

We have performed similar analyses for most of the major cancer sites and found a significant inverse relation to income level for only a few sites other than those considered here. Thus our results do not appear to reflect a general cancer susceptibility among the lower income population or to be an artifact of census underenumeration in that group.

APPENDIX

The scheme for assigning scores to the patterns of cancer incidence with increasing income level within each age group and geographic area is shown in appendix table 1.

For example, if incidence rates increased consistently as income levels increased, a score of +2 was assigned. Conversely, if rates decreased as income levels increased, a score of −2 was assigned. Summing over age groups within each TNCS area gives a range of possible values of −6 to +6. The expected value of the score calculated under the assumption of no association between cancer incidence and socioeconomic status is 0.0 and the variance is 2.0, since each ordering is equally likely ($P=1/6$). If a tie occurred, a probability distribution under the null hypothesis was generated that accounted for the tie. If rates for all three income levels within a given age group were identical, the age group was dropped from the analysis. This situation rarely occurred.

The scores across the nine geographic areas were then added, resulting in a single score between −54 and +54 that summarized the overall association while "controlling" for any influences due to heterogeneity in socioeconomic levels. To calculate the significance levels, we used an approximation. If X represents the summary score over m areas, then $P(X \leq -k) = P(X \geq k) = P(Z > [k-0.5]/\sqrt{6m})$, where Z has a standard normal distribution. For example, if $m=9$ and the score is 16, then $P(X \geq 16) = P(Z \geq 2.111) = 0.017$.

Glycoconjugate With *Ulex europaeus* Agglutinin-I-Binding Sites in Normal Mucosa, Adenoma, and Carcinoma of the Human Large Bowel[1,2]

Suguru Yonezawa,[3] Takao Nakamura,[3] Sadao Tanaka,[3] *and* Eiichi Sato[3,4]

ABSTRACT—Cancerous lesions and nonneoplastic mucosa of surgically extirpated specimens from 94 patients with colorectal carcinoma (of the right colon, 31 patients; of the left colon, 29 patients; and of the rectum, 34 patients) and endoscopically polypectomized specimens from 18 patients with rectal adenoma were examined with fluorescein isothiocyanate-conjugated or horse-radish peroxidase-conjugated *Ulex europaeus* agglutinin-I (UEA-I) specific to a certain terminal α-L-fucosyl residue in glycoconjugates. Of the 31 patients with right colon cancers, 22 showed positive UEA-I binding in the neoplastic cell apexes, apical luminal borders, and luminal secretions. The adjacent nonneoplastic mucosa of all 31 patients, however, demonstrated positive UEA-I binding in the goblet cell mucus. UEA-I binding was positive for 23 of the 29 left colon cancers and for 28 of the 34 rectal cancers, although UEA-I binding was not revealed in the adjacent nonneoplastic mucosa for most of the cases. Of the 18 rectal adenomas, 12 specimens showed positive UEA-I binding in the apical secretions of their adenoma cells. Marked regional differences of UEA-I binding in the nonneoplastic mucosae indicated that the constituents of glycoprotein with UEA-I binding sites in goblet cell mucus differed significantly between the human right and left large bowels. Positive UEA-I binding in many rectal cancerous and adenomatous lesions suggested that a neoplastic glycoprotein with α-L-fucosyl residue was produced or that the terminal carbohydrate structure of glycoprotein present in the nonneoplastic mucosa was altered to bind easily with UEA-I after the neoplastic transformation had occurred. A possible relation of this UEA-I binding to blood group H(O) substance is discussed.—JNCI 1982; 69:777–785.

Glycoproteins are the major components of secreted mucins and of membranes of the gastrointestinal mucosa. Histochemical studies in which stains such as periodic acid–Schiff, Alcian blue, high-iron diamine, and high-iron diamine–Alcian blue have been used have demonstrated mucosubstances in human colon mucosa. The histochemical investigations have suggested either qualitative and quantitative differences in carbohydrate content between the proximal and distal portions of the colon (*1–4*) or considerable alterations in the carbohydrate contents of mucinous glycoproteins in colorectal cancerous and adenomatous lesions (*3–6*). However, these staining procedures do not discriminate a specific carbohydrate sequence in glycoconjugates in normal mucosa or in neoplastic lesions.

Lectins derived from plants or animals have an ability to bind with specific carbohydrate residues of glycoconjugates (*7*). Recently, FITC or HRP conjugates of lectins have been used for investigation of tissue sections (*8–12*). We used lectins to study glycoprotein in nonneoplastic mucosa and neoplastic lesions of the specimens of human colorectal carcinoma, and we found specific and interesting features of binding of UEA-I specific to a certain terminal α-L-fucosyl residue (*13, 14*) in both nonneoplastic mucosa and neoplastic lesions. In this study, regional differences of glycoprotein with UEA-I receptors in nonneoplastic colorectal mucosa were noted; furthermore, alteration of glycoprotein following neoplastic change is discussed.

MATERIALS AND METHODS

Surgically extirpated specimens were examined from 94 patients with colorectal carcinoma [of the right colon (cecum and ascending colon), 31 patients; of the left colon (descending and sigmoid colons), 29 patients; and of the rectum, 34 patients], and endoscopically polypectomized specimens were examined from 18 patients with rectal adenoma.

Staining with FITC–lectins.—Surgical specimens of neoplastic or nonneoplastic portions from the patients with colorectal carcinoma and adenoma were either fixed in Formalin or frozen in Dry Ice–acetone. The Formalin-fixed specimens were embedded in paraffin, cut at 4 μm, deparaffinized, rehydrated, and washed four times in PBS (pH 7.2) for 5 minutes each. The frozen specimens were cut in a cryostat, dried in air, fixed in acetone for 1 minute, and washed four times in PBS. These tissue sections were incubated with FITC-conjugated plant lectins for 30 minutes at room temperature. The lectins used as the FITC-conjugated materials were Con A, WGA, *Bauhinia purpurea* agglutinin, *Ricinus communis* agglutinin-I, and UEA-I, all of which were purchased from E-Y Laboratories, Inc., San Mateo, Calif. The concentration of all lectins was 1 mg lectin/ml. The tissue sections were then washed four times in PBS and examined under a fluorescence microscope with epi-illumination (Olympus, model BH-RFL-LB) in which the excitation interference filter IF 490 and dichroic mirror reflector DM 500 containing absorption filter O 515 were used. Photographs were taken with Fujichrome 100 daylight film. For control inhibition studies, 0.2 *M* of the appropriate

competing sugars was mixed in the incubation solutions (α-methyl-D-mannoside for Con A, *N*-acetyl-D-glucosamine for WGA, *N*-acetyl-D-galactosamine for *Bauhinia purpurea* agglutinin, β-lactose for *Ricinus communis* agglutinin-I, and α-L-fucose for UEA-I).

Staining with HRP–UEA-I.—The Formalin-fixed, paraffin-embedded sections were incubated with HRP-conjugated UEA-I (E-Y Laboratories, Inc.) for 30 minutes at room temperature, after endogenous peroxidase activity of the sections had been blocked by treatment of the sections with methanol and H_2O_2 (*15*). The sections were then washed four times in PBS and stained with 3,3′-diaminobenzidine as described by Graham and Karnovsky (*16*).

RESULTS

As a first experiment, we used the five FITC-conjugated lectins listed in "Materials and Methods" to do lectin-binding studies on Formalin-fixed surgical specimens of 15 human colorectal carcinomas (of the right colon, 5 cases; of the left colon, 5 cases; and of the rectum, 5 cases). The lectin-binding studies indicated that only UEA-I presented an evident difference in the labeling behavior of goblet cell mucus of nonneoplastic mucosa when the right and left large bowels were compared (figs. 1A, 1B). The other four lectins did not show regional differences in their labeling patterns. Therefore, we examined UEA-I binding further in nonneoplastic mucosa and neoplastic lesions from 112 patients, of whom 94 had carcinomas and 18 of whom had adenomas.

To elucidate the influence of Formalin fixation and paraffin embedding on UEA-I binding, we did comparative UEA-I-binding studies on both fresh (unfixed)-frozen sections and Formalin-fixed, paraffin-embedded sections prepared from adjacent tissues of the frozen sections. These specimens were obtained from nonneoplastic portions and neoplastic lesions in 6 extirpated specimens of colorectal carcinoma (from 3 cases each of the right colon and of the rectum). Fresh-frozen sections and Formalin-fixed, paraffin-embedded sections of the 6 specimens showed identical results with regard to the UEA-I binding with goblet cell mucus in the nonneoplastic mucosa or with cell apexes, apical luminal borders, and luminal secretions in the neoplastic lesions. Therefore, we concluded that conventional Formalin-fixed, paraffin-embedded specimens were useful in the UEA-I-binding study within the limits of nonneoplastic goblet cell mucus or neoplastic cell apexes, apical luminal borders, and luminal secretions.

However, we noted some discrepancies between frozen sections and paraffin sections: Fresh-frozen sections from the 6 colorectal carcinoma cases demonstrated evident UEA-I binding with capillaries and blood vessels and very weak UEA-I binding with epithelial cell membranes, but Formalin-fixed, paraffin-embedded sections from these 6 cases did not demonstrate such bindings. However, in the following series of UEA-I-binding studies of many other surgical specimens, UEA-I binding with capillaries and blood vessels was at times observed even in the Formalin-fixed, paraffin-embedded sections (fig. 6), although binding with the cell membranes was never observed in the Formalin-fixed, paraffin-embedded sections of this series.

On the basis of the above-mentioned data, we used both FITC-conjugated UEA-I and HRP-conjugated UEA-I to examine surgically extirpated specimens from 94 patients with colorectal carcinoma and endoscopically polypectomized specimens from 18 patients with rectal adenoma. Sections treated with both FITC-conjugated UEA-I and HRP-conjugated UEA-I showed identical results. The UEA-I binding was inhibited by incubation with 0.2 *M* α-L-fucose, as shown in figure 1C.

The results of UEA-I-binding studies on nonneoplastic mucosae and neoplastic lesions of the 94 patients with colorectal carcinoma are summarized in table 1. The data by case are shown in text-figure 1. The extent of cancerous lesions was not correlated with the degree of UEA-I binding.

Right colon (cecum and ascending colon).—Most of the goblet cell mucus (20 patients) and some of the goblet cell mucus (11 patients) were bound with UEA-I in the nonneoplastic mucosae of the 31 patients with right colon cancer. There was no patient from whom the goblet cell mucus of the nonneoplastic mucosa was not labeled by UEA-I.

In the cancerous lesions of these 31 patients, most of the neoplastic cell apexes, apical luminal borders, and luminal secretions were bound with UEA-I (10 patients) (fig. 2); however, some of the neoplastic cell apexes, apical luminal borders, and luminal secretions were labeled by UEA-I (12 patients). No binding of UEA-I with neoplastic cell apexes, apical luminal borders, or luminal secretions was found in the remaining 9 patients, although most if not some of their nonneoplastic goblet cell mucus revealed UEA-I binding (fig. 3). In these cases, UEA-I selectively bound with nonneoplastic goblet cell mucus but did not label neoplastic secretions (fig. 4A), although the other four lectins (i.e., excluding UEA-I) labeled both secretions of the nonneoplastic mucosa and neoplastic lesion (fig. 4B).

Left colon (descending colon and sigmoid colon).—Goblet cell mucus of the nonneoplastic mucosa of the left colon in 26 of 29 patients was never labeled by UEA-I, whereas some of the unaffected goblet cell mucus in the remaining 2 patients and most of it in the other patient was bound with UEA-I.

In the cancerous lesions, most of neoplastic cell apexes, apical luminal borders, and luminal secretions were bound with UEA-I in 14 patients, and some of the neoplastic cell

TABLE 1.—*UEA-I binding in nonneoplastic mucosa and carcinoma of the human large bowel*

Bowel tissue	UEA-I binding[a]		
	−	+	++

TEXT-FIGURE 1.—UEA-I binding in the nonneoplastic mucosa and in the carcinoma in specimens from each patient with colorectal carcinoma. Data are presented by case.

apexes, apical luminal borders, and luminal secretions were labeled in 9 patients. The cancerous lesions of the remaining 6 patients showed no binding of UEA-I.

Rectum.—None of the goblet cell mucus of the nonneoplastic rectal mucosa of any of the 34 patients was bound with UEA-I. In the cancerous rectal lesions, most of neoplastic cell apexes, apical luminal borders, and luminal secretions in 14 of the patients and some of the neoplastic cell apexes, apical luminal borders, and luminal secretions in 14 patients were bound with UEA-I (fig. 5). The cancerous lesions in the remaining 6 patients showed no UEA-I binding.

In the 18 polypectomized specimens of rectal adenoma, most of the neoplastic apical secretions of 2 of the patients and some of the secretions in 10 of the other patients were labeled by UEA-I. The remaining specimens of the other 6 patients showed no UEA-I binding. In addition, adenomatous lesions were combined with carcinoma in several patients with rectal cancer. In the contact points of adenomatous lesions and nonneoplastic mucosae in these patients, UEA-I labeled only the neoplastic epithelium but did not label the nonneoplastic mucosa (fig. 6).

DISCUSSION

This UEA-I-binding study of the nonneoplastic mucosa of human colon and rectum demonstrated an obvious difference between UEA-I receptors in the nonneoplastic goblet cell mucus of the right large bowel and the UEA-I receptors in the nonneoplastic goblet cell mucus of the left large bowel. In all specimens of the right colon, some if not most of the UEA-I receptor was in the nonneoplastic goblet cell mucus. However, most of the left colon and rectum specimens (from 60 of 63 patients) had no UEA-I receptor in their nonneoplastic goblet cell mucus. It is especially noteworthy that no nonneoplastic goblet cell mucus in any specimen of the rectal mucosa had the UEA-I receptor.

Terminal positions on the oligosaccharide side chains are generally occupied by sialic acid or fucose (*17, 18*). These two sugars compete with each other for occupation of the terminal positions (*19*). In chemical studies of secretions from a normal human, Hoskins and Zamcheck (*20*) showed a significantly greater sialic acid content and a lower fucose content in rectal mucus. As UEA-I is specific to a terminal fucosyl residue (*13, 14*), the lack of UEA-I binding with rectal mucus may be related to the low fucose content in the rectum.

Culling et al. (*21*) histochemically demonstrated O-acylated sialic acids in the epithelial mucins of the lower end of the gastrointestinal tract, and they also reported an increase in periodic acid–Schiff reactivity after saponification, by which the sialic acids are removed. Therefore, the differing intensity of periodic acid–Schiff stain between the proximal and the distal colon, which has been observed in previous histochemical studies (*2–4*), is probably related to the presence of the sialic acids that compete with fucose for the occupation of the terminal positions on sugar side chains; therefore, the differences in intensity may not be directly related to fucose content.

Essner et al. (*9*) used fluoresceinated lectins to study the location of carbohydrate components in the colon of rats. They studied only the descending colon; the proximal colon was not examined. Freeman et al. (*22*) used lectins to detect goblet cell glycoconjugate differences in the proximal and distal colons of rats, tissues of which had been fixed in a modified Bouin's solution containing picric acid, formaldehyde, and acetic acid. They reported an apparent regional difference in binding of Con A and *Lens culinaris* agglutinin, which are specific to mannosyl or glucosyl residues, in the goblet cell mucus of normal colon mucosae of the rats. Labeling of the two lectins with goblet cell mucus was observed only in the proximal colon and not in the distal colon, whereas UEA-I did not show regional differences in the rats examined in this study (*22*). However, in the human colorectal specimens, only UEA-I showed an apparent regional difference in the labeling behavior of goblet cell mucus between the right and left large bowels (figs. 1A, 1B), inasmuch as Con A did not reveal any regional difference. These interspecies differences must be accounted for in the comparison of experimental animal with human specimens.

Because Cazal and Lalaurie (*23*) showed that extracts of *Ulex europaeus* seed contain a protein that reacts with blood group H(O) antigen, the *Ulex* extracts have been used for studies of the blood group H(O) substance in human tissues (*24–31*). The H(O) antigen is considered to be a precursor substance of A or B antigens and is present not only in human blood group O but also in human non-O blood groups (*32*, 33). Therefore, an investigation of the H(O) antigen may be basic and valuable in studies of blood group substances in human tissues, irrespective of the A-B-O blood groups. However, as some authors described (*24–26, 28, 31*), the *Ulex* extracts used in the earlier studies had questionable specificity and sensitivity; consequently, the results are inconclusive. Also, in the earlier studies of human colon, the blood group H(O) substance had not been successfully investigated, although blood group A and B substances were well demonstrated (*24, 25, 28, 34–36*). Our present study could well detect UEA-I receptors in nonneoplastic mucosae and neoplastic lesions of human large bowels. The UEA-I receptors may be a blood group H(O) substance, because the mode of distribution of UEA-I receptors is similar to those of A or B substances (*24, 25, 28, 34–36*).

Many of the rectal cancers revealed positive UEA-I binding in their neoplastic cell apexes, apical luminal borders, and luminal secretions in spite of negative UEA-I binding in the adjacent nonneoplastic mucosa (fig. 5). Although these findings probably indicate that blood group H(O) substances appear in the cancerous lesions, it is undeniable that a neoplastic glycoprotein with terminal α-L-fucosyl residue which does not belong to the blood group H(O) substance is produced or that the terminal carbohydrate structure of glycoprotein present in the nonneoplastic mucosa is altered to a form that binds easily with UEA-I.

Kim and Isaacs (*37*) noted that the level of fucose was significantly reduced in the colon cancer tissue as compared with normal human colon mucosa. Their data are concerned with a total amount of fucose in the tissue, but the results obtained by our UEA-I binding study are concerned only with a certain terminal α-L-fucosyl residue. Therefore, the data in our study and the data of Kim and Isaacs are not comparable. However, the obvious difference between the UEA-I binding in the nonneoplastic mucosa of the human right and left large bowels must be accounted for in studies of fucose content of human colorectal mucosa.

Two-thirds of the 18 rectal adenoma patients showed positive UEA-I binding in their neoplastic epithelium, in spite of the negative UEA-I binding in the nonneoplastic rectal mucosae of the previously mentioned 34 patients with rectal cancer. In the contact points of adenomatous lesions combined with carcinoma and the adjacent nonneoplastic mucosa in the rectum, UEA-I binding clearly distinguished the adenomatous lesions from [illegible] adjacent nonneoplastic mucosa, as shown in figure 6. Because malignant potentiality of colorectal adenoma has been noted (*38–41*), we were interested to note that the solitary adenomas and the adenomatous lesions combined with carcinomas were labeled by UEA-I. This suggests either the appearance of blood group H(O) substance, the production of neoplastic glycoprotein, or the alteration of the terminal carbohydrate structure of glycoprotein in the adenomas similar to those of the cancerous lesions discussed above.

Cancerous cells or embryonic cells are known to have different spectra of glycoconjugates as compared with their normal or differentiated counterparts (*42–44*). These differences are caused either by incomplete glycosylation in cancerous cells or by formation of additional sugar chains in such cells. We are especially interested to know which mechanism operates in the altered expression of UEA-I receptors in malignant cells. Further studies on the biochemical nature of glycoconjugates labeled with UEA-I and a detailed investigation of the correspondence between the histologic findings and the glycoconjugate distribution in adenomatous and cancerous lesions may reveal the process by which glycoconjugates are alterated as an accompaniment to malignant transformation in the human colorectal region.

Cerebrospinal Fluid Markers in African Burkitt's Lymphoma With Central Nervous System Involvement[1,2]

William C. Wallen,[3,4] Robert J. Biggar,[5] Paul H. Levine,[6] Janet Neequaye,[7] *and* Francis K. Nkrumah[7,8]

ABSTRACT—Several cerebrospinal fluid markers were found to be elevated in Burkitt's lymphoma patients with central nervous system (CNS) involvement. Antibody levels to the virus capsid antigen of the Epstein-Barr virus and to the brain cell antigens myelin and cerebroside were elevated during active CNS disease. Immune complexes were present in levels above 100 µg/ml in most patients with CNS involvement but tended to be low or negative in patients without CNS disease. Oligoclonal IgG bands were present in 12 of 13 patients with CNS disease and in only 3 of 26 patients with no clinical evidence of disease. None of these markers were present in 6 other tumor patients without CNS disease. The presence of these markers in 12 of 13 patients in whom CNS disease was involved suggests that these markers may be useful in determining the status of the tumor with regard to involvement of the CNS.—JNCI 1982; 69:787–792.

BL is a B-cell cancer endemic in Africa (*1*) and New Guinea (*2*). It typically involves the abdomen and/or facial bones of young children (*3*) and frequently involves the CNS either at initial presentation or at relapse (*4*).

The association of EBV with Burkitt's tumors has been demonstrated by serologic (*5*) and antigenic (*6*) studies and by detection of EBV DNA by nucleic acid hybridization (*7*, *8*). Although the etiology of BL remains to be determined, the association of EBV with these tumor cells is well established.

The involvement of the CNS in BL may be difficult to diagnose when few cells are present or when the patient has neuropathy but no pleocytosis. When the CNS becomes involved, the prognosis is poor and treatment is generally unsuccessful (*9*). Markers that identify CNS involvement would be useful in the diagnosis and prognosis of CNS disease as well as in the monitoring of chemotherapy. Previously, we found oligoclonal IgG bands in CSF of African BL patients with CNS involvement but not in patients without CNS disease (*10*). Oligoclonal IgG bands are a variable number of abnormal discrete protein bands that appear in the γ-globulin region in polyacrylamide gel electrophoresis patterns. These bands are seen in such CNS diseases as subacute sclerosing panencephalitis (*11*), multiple sclerosis (*12*), and other virus-induced CNS diseases (*13*, *14*) and have also been reported in 5 children with medulloblastoma (*15*). In this study we report our findings from an examination of CSF from African BL patients for several parameters of CNS involvement including CSF antibodies to EBV antigens, antibodies to the brain antigens myelin and cerebroside, antigen-antibody complexes, and oligoclonal IgG. We analyzed serial samples taken from BL patients with CNS involvement during their therapeutic treatment schedule. We found a good correspondence between CNS involvement by the tumor and the presence of some of these biologic markers in the CSF.

MATERIALS AND METHODS

Patients.—Patients were seen in the African Burkitt Tumor Project, University of Ghana Medical School. Each patient was examined thoroughly and his and her BL was confirmed by biopsy according to accepted criteria (*16*). Involvement of the CNS by the tumor was assessed by clinical criteria and by examination of CSF. When the patient initially presented with the disease and during therapy for each tumor occurrence, lumbar puncture was performed for evaluation and therapy (either prophylactic or therapeutic). Evaluation of the CSF included protein determinations and cytology with greater than 10 cells. The presence of blast cells was considered abnormal. Serial samples were obtained from patients undergoing treatment for CNS disease. The remaining CSF was frozen at −20°C and shipped to the National Institutes of Health where they were tested under code for biologic markers.

Of 39 African BL patients, 13 were diagnosed as having CNS involvement on the basis of symptoms (ataxia, paraplegia, ophthalmoplegia, headaches, and dizziness) and/or other signs (elevated CSF protein, increased numbers of CSF lymphocytes, and/or the presence of blast cells in the CSF). In addition, 6 patients in the same age range but having other diseases not involving the CNS served as a control group. Patients with BL routinely received a systemic therapeutic regimen that varied according to tumor extent and response but always included at least three courses of cyclophosphamide; some patients also received

vincristine and cytosine arabinoside (dose varied with regimen). Those patients with CNS involvement received intrathecal therapy consisting of 10 mg methotrexate daily for 4 days with each course. Prophylactic intrathecal therapy for those without clinically apparent CNS involvement was 15 mg methotrexate given once with each course of septicemic chemotherapy.

Antibody assays.—The CSF samples were evaluated for antibody to EBV VCA and EBNA by indirect immunofluorescence (*5, 6*). Antibodies to myelin and cerebroside were assayed by an enzyme-linked immunosorbent assay previously described (*17*). Myelin was provided by Dr. G. DeVries (Medical College of Virginia, Richmond, Va.) and was obtained according to an established procedure from human minced white matter that was homogenized and purified on a discontinuous sucrose density gradient (*18*). The myelin had enzymatic properties consistent with those of myelin obtained by procedures of Norton and Poduslo (*19*). Cerebroside was obtained from bovine brain (Sigma Chemical Corp., St. Louis, Mo.). Each antigen was concentrated to 1 mg/ml, added to 96 flat-well microtiter plates at 100 µl/well, and absorbed for 15 hours at 4°C. We removed unabsorbed antigen by washing the wells with phosphate-buffered saline (pH 7.4). Patient CSF was added in 50-µl volumes to appropriate wells and was incubated at 37°C for 90 minutes. After the wells were washed, goat anti-human IgG conjugated with alkaline phosphatase (Sigma Chemical Co.) was added to the wells and incubated for 60 minutes at 37°C. The color reaction was obtained by the addition of *p*-nitrophenylphosphate as substrate for 30 minutes at 37°C. The reaction was halted with 3 *M* NaOH, and the optical density was read at 405 nm in an automated plate reader (Titertek Multiscan; Flow Laboratories, McLean, Va.).

Immune complexes.—The levels of immune complexes were determined by a radioimmune Raji cell assay according to the procedure of Theofilopoulos et al. (*20*). In this assay, 75 µl of CSF was mixed with 25 µl of fresh BALB/c mouse serum (diluted 1:20) and incubated at 37°C for 30 minutes. Raji cells (4×10^7 cells/ml) were added to the samples in 50-µl volumes and incubated at 37°C for 45 minutes. The mixture was then washed three times and incubated with 25 µl of ^{125}I-labeled goat anti-human IgG (Cappel Laboratories, Cochranville, Pa.) for 30 minutes at 4°C. The samples were then washed three times and enumerated in a Packard gamma counter. Samples were analyzed with the use of a standard curve of aggregated IgG to compare equivalent radioactivity bound to the Raji cells. Results are presented as microgram equivalents of bound aggregated IgG per milliliter of CSF.

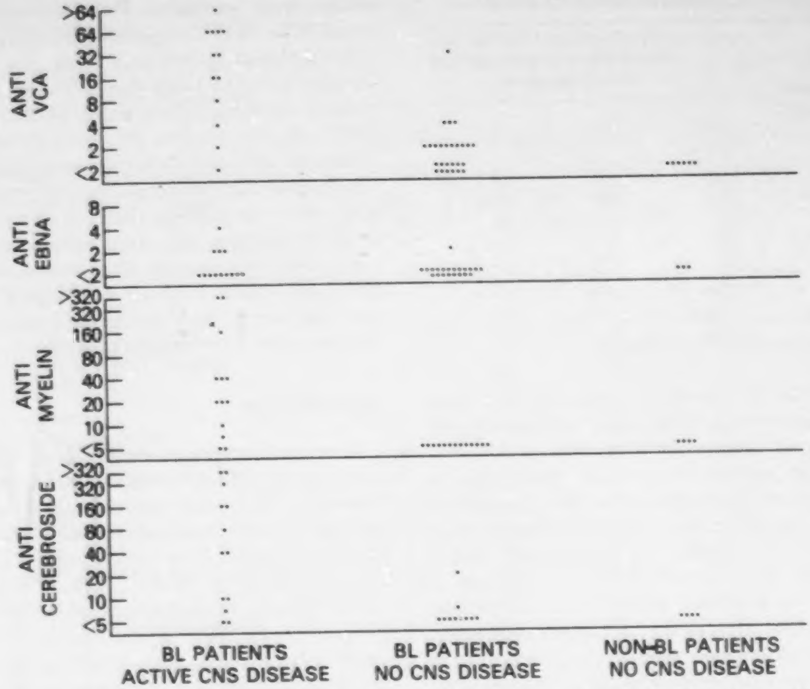
Oligoclonal IgG.—The oligoclonal IgG in CSF was detected by use of an SDS-polyacrylamide gel electrophoresis procedure as previously described (*21*). Electrophoresis was performed on vertical slab gels of 7% acrylamide with a 9% separating gel for 12 hours at 4°C with a constant current of 20 milliamperes per gel. Samples of CSF (50 µl) were mixed with 50 µl of electrophoresis buffer (2 parts 70% sucrose with bromophenol blue and 1 part 10% SDS) and were incubated at 37°C for 15 minutes. Samples were then heated at 100°C for 3 minutes and electrophoresed at 50 µl/lane. The gel protein bands were then stained with Coomassie brilliant blue. Two or more distinct bands that appeared in the γ-globulin region of the gel were considered positive. The IgG nature of the bands was confirmed by surface immunofixation with an indirect immunoenzyme procedure described previously (*20*). Strips of cellulose acetate membrane coated with solid-phase absorbed goat anti-human IgG (γ-chain-specific; Cappel Laboratories, Cochranville, Pa.) were overlaid on the gel for 4 hours at 37°C. The gels were washed for 15 hours at 4°C with multiple changes. Peroxidase-conjugated rabbit anti-goat IgG (Miles-Yeda Ltd., Rehovot, Israel) was used to detect the antihuman–human IgG complex. The bands were identified by a substrate–diaminobenzidine–indicator that precipitated on the IgG bands.

RESULTS

Of the 39 BL patients, 13 had CNS disease associated with the primary tumor that occurred at presentation or developed during the course of the study. The 6 non-BL patients had no indications of CNS disease. A comparison of the antibody levels in CSF to EBV VCA and EBNA as well as the brain cell antigens myelin and cerebroside showed that most BL patients with active CNS involvement had antibody levels to EBV VCA, myelin, and cerebroside but not to EBNA. These results are presented in text-figure 1, where the highest values obtained from any of the serial samples tested were used to make up the composite graphs. Among BL patients without CNS disease, 22 of 26 (85%) had EBV VCA titers of 1:2 or less, 3 had titers of 1:4, and 1 had an elevated titer of 1:32. All 6 of the non-BL patients were negative for antibody to EBV VCA. Of the 13 BL patients with active CNS disease, 10 of 13 (77%) had elevated anti-VCA antibody (ranging from 1:8 to 1:512) in their CSF. The CSF levels of antibody to EBNA were not significant in any of the groups. Only 4 of 13 (31%) patients with CNS disease had any titer (ranging from 1:2 to 1:4), and only 1 of 26 (4%) without CNS disease had detectable EBNA antibody. None of the patients without CNS disease (BL and non-BL) had antibody to myelin, and only 1 of the BL patients had a significant titer against cerebroside (1:20). Among BL patients with active CNS disease, 11 of 13 (85%) had antibody to both myelin (ranging from 1:5 to 1:640) and cerebroside (ranging from 1:5 to 1:2560) at the time of active disease.

Immune complex levels were also elevated in the CSF of patients with CNS disease (text-fig. 2). Non-BL patients had low CSF immune complex levels, which ranged up to 32 µg with levels for 3 of 6 patients being undetectable. Among BL patients without CNS disease, none had CSF immune complex levels over 100 µg, and only 4 of 26 (15%) had levels over 50 µg. However, among 13 BL patients with active CNS involvement, all had detectable levels of immune complexes (ranging from 18 to 248 µg) and 9 of the 13 (69%) patients had immune complex levels over 100 µg.

Of the 13 BL patients with active CNS disease, 12 (92%) had oligoclonal IgG bands in their CSF that numbered from 2 to 5 (table 1). Ten cases of the 13 with CNS disease were seen prior to the development of CNS involvement, and 8

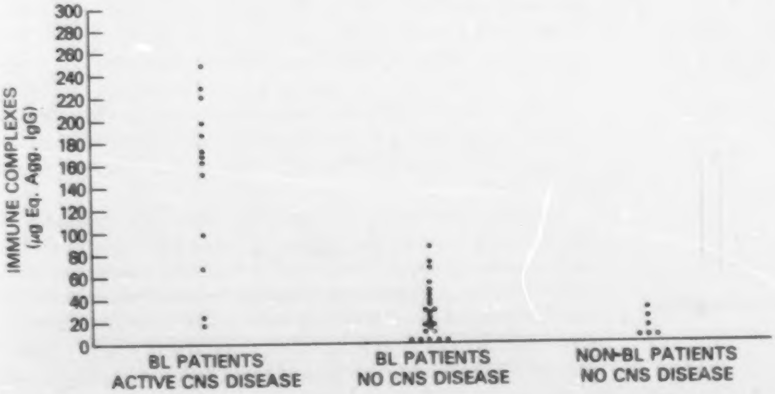


TEXT-FIGURE 1.—CSF levels to EBV VCA, EBNA, and the brain cell antigens myelin and cerebroside in BL patients with active CNS disease, in BL patients without CNS disease, and in non-BL patients without CNS disease.

of these BL cases did not have these bands upon initial sampling but developed them only at the time of CNS involvement by the tumor. Among the 26 BL patients without CNS symptoms or signs, only 3 (12%) had oligoclonal IgG (band numbers ranging from 2 to 3) and 23 were negative. None of the non-BL patients had these bands in their CSF.

The frequency of positive CNS markers is summarized in table 2. None of the non-CNS-involved non-BL patients had significant levels of CSF activity with these markers. Among BL patients without CNS involvement, a few (up to 15%) had elevated levels of one of the CSF markers. Most of the patients with CNS disease (≥69%) had positive responses with each of these CSF markers except EBNA.

Multiple samples of CSF were collected from the 13 patients with CNS disease during their chemotherapy to examine for reactivation of disease. Results from serial samples from these patients are presented in table 3 along with their clinical status. Samples were obtained from 10 patients (#1–9 and #13) prior to CNS involvement and from 3 patients (#10–12) first seen with CNS disease. In the samples from the 10 patients obtained prior to CNS disease onset, the VCA antibody was low or negative (≤2) in all except patient #7 and increased in titer as the CNS became involved except for patient #9. Patient #7 had a relatively high VCA titer and retained this level throughout the testing. Patient #9 had no clinical indication of CNS in-



TEXT-FIGURE 2.—Immune complexes detected by Raji cell radioimmunoassay in CSF of BL patients with and without CNS disease and in non-BL patients without CNS disease. Eq. Agg.=equivalents of aggregated IgG.

TABLE 1.—*Oligoclonal IgG bands in CSF of BL patients*

Patients	CNS involvement	No. of patients	No. of patients with the following No. of oligoclonal IgG bands:				
			0	2	3	4	5
BL							
CNS disease	Prior[a]	10	8	1	0	1	0
	Active	13	1	2	5	4	1
No CNS disease	None	26	23	1	2	0	0
Non-BL							
No CNS disease	None	6	6	0	0	0	0

[a] Prior to the development of CNS involvement.

CSF antibody to VCA, no antibody responses to brain antigens, low or negative levels of immune complexes, and no oligoclonal IgG bands despite 530 blast cells in the CSF.

Antibodies to myelin and cerebroside also were negative in 5 of 8 patients tested when samples were obtained before CNS disease and became positive at the time clinical signs and/or symptoms became evident. In patients #3 and 4 antibody to myelin was detected before clinical evidence of disease was present, patients #5 and 6 had insufficient initial samples for testing, and patient #9 never developed antibody to either brain antigen during the disease. In 2 (patients #11 and 12) of 3 patients (#10–12) in whom CNS disease was already evident at the time of sampling, antibody to myelin was already present. (The third patient, #10, was not tested on the first sample because of insufficient CSF.) In general, the level of antibody did not progress with disease and often was higher during initial phases of CNS disease and frequently decreased during later attacks of the disease or when the patient was near death.

Immune complex levels were low in 7 patients (#1, 3–7, and 13) prior to CNS disease onset and progressively increased with CNS disease. In patients #2 and 8 the immune complexes were initially high, whereas the other parameters and clinical signs were negative or low. Patient #9 had low levels of immune complexes throughout the disease. Among the 3 patients initially seen with CNS disease, 2 (#11 and 12) had significant immune complex levels that remained elevated during CNS involvement and tended to subside with disease remission. Patient #10 developed barely detectable levels of complexes during the period of testing.

TABLE 2.—*CSF markers of CNS involvement in BL and other tumors at the time of active disease*[a]

Antibody responses	No. of non-CNS-involved BL patients with markers (%)[b]	No. of CNS-involved BL patients with markers (%)[c]
EBV		
VCA (≥1:4)	4 (15)	11 (85)
EBNA (≥1:2)	1 (4)	4 (31)
Myelin (≥1:5)	0 (0)	11 (85)
Cerebroside (≥1:5)	1 (4)	11 (85)
Immune complexes (≥50 μg)	4 (15)	11 (85)
Oligoclonal IgG bands (≥2)	3 (12)	12 (92)

[a] Of the 6 non-CNS-involved non-BL patients, none had significant levels of CSF activity with these markers.

[b] There were 26 non-CNS-involved BL patients.

[c] There were 13 CNS-involved BL patients.

Oligoclonal IgG bands were not detected in 8 of 10 samples prior to CNS disease onset. Seven patients subsequently developed these bands at the time, or just following, CNS invasion. Patient #9 never developed these bands. In 2 patients (#5 and 7) bands were found at initial examination before clinical signs and/or symptoms became evident and before the patients received any chemotherapy. In each of the 3 patients who were initially seen with CNS symptoms, none had these bands at that time but all subsequently developed them. Patient #4 initially was negative for oligoclonal bands, developed 3 IgG bands at the time of CNS disease onset, but became negative for the bands at death.

DISCUSSION

The involvement of the CNS by African BL results in a particularly difficult stage of the disease for diagnosis and treatment. This study demonstrated that several parameters of tumor activity were altered as the CNS became involved. Immunofluorescent antibody levels to EBV VCA became elevated (≥1:8) in 10 of 13 patients with active CNS disease and in general tended to increase in titer as the CNS disease progressed. Because serum antibody levels to EBV VCA tend to be much higher in BL patients (*5*) than in other lymphoma patients, it was impossible to determine whether the moderate levels of antibody in the CSF were due to in situ synthesis of EBV antibody or diffusion across the blood-brain barrier. Possibly, the tumor cells as they invaded the CNS altered the blood-brain barrier and caused an increased permeability for EBV VCA antibody. It is also possible that the prophylactic or therapeutic use of intrathecal methotrexate contributed to elevating some of these biomarkers. However, the findings in patients with CNS disease who were studied before any intrathecal treatment, (i.e., patient #11 and 12) were similar to those in patients who later developed CNS disease. We believe, therefore, that the biomarkers do reflect disease activity and are not simply a reaction to therapy.

Antibodies to brain cell constituents (myelin and cerebroside) were present in 12 of 13 patients with active CNS disease but rarely occurred in BL patients or non-BL patients without CNS disease. The responses to these brain antigens were frequently quite similar and could overlap inasmuch as cerebroside is an integral component of myelin. These antibody titers did not appear to progress with disease, which suggests that they indicate disruption of brain cells themselves but are unrelated to the degree of tumor cell involvement. Why individuals develop these autoantibodies at all and how much brain cell disruption occurs during CNS involvement with this tumor remain to be determined.

Immune complexes in the CSF were also elevated in active CNS disease but not in the non-CNS-involved BL and non-BL groups. The levels of immune complexes generally increased in patients with CNS disease at the time of active CNS involvement and were lower at times when no CNS disease was present or when the patient was in clinical remission. However, 3 of the patients developed CNS disease

and had little or no immune complexes in their CSF. Two patients died abruptly with CNS symptoms and 1 patient went into a complete remission, possibly before significant levels of complexes could form.

The relationship of oligoclonal IgG in the CSF and in CNS disease in BL patients was more consistent. Twelve of 13 patients with CNS disease developed oligoclonal bands in their CSF compared to 3 of 26 patients without CNS involvement. More important, 2 patients had the bands at initial examination before any chemotherapy, which suggested that this marker was also disease related. Finding up to 12% of the patients without overt CNS disease but with bands suggests that these patients should be watched for development of CNS involvement. No direct relationship between the numbers of bands and CNS disease progress could be determined, although most of the patients developed these bands concomitant with the development of CNS disease. Only patient #9 in this study failed to develop bands, which may have been a result of insufficient time for their production because CNS involvement was found only 3 days before this patient died.

These CSF markers were of some value for the determination of CNS involvement by African Burkitt's tumor cells in most patients with CNS disease. In these cases, however, the findings should be interpreted with the fact in mind that a virus association has been proposed for this tumor, which distinguishes it from other lymphoma forms. There was a clear distinction between the presence of antibody to EBV VCA and brain cell antigens, immune complexes of over 100 μg/ml, and oligoclonal IgG in the CSF of patients with CNS disease compared to those without any CNS involvement. Only 1 patient (#9) with CNS disease did not express any of these CSF markers, and this patient died just after CNS disease onset. Some patients may show these markers without apparent CNS signs or symptoms, but it is possible that CNS disease did occur but went undetected. Therefore, although not necessarily diagnostic, these markers would be useful in those patients in whom CNS disease is suspected and also may be useful in the monitoring of the progress of chemotherapy for CNS disease in this tumor system.

Transforming Growth Factors in the Urine of Normal, Pregnant, and Tumor-Bearing Humans[1,2]

Daniel R. Twardzik,[3,4] Stephen A. Sherwin,[5] Jane Ranchalis,[3] *and* George J. Todaro[3,6]

ABSTRACT—Transforming growth factor (TGF) activities could be detected in the urine of normal, pregnant, and tumor-bearing humans. These acid- and heat-stable polypeptides competed for binding to epidermal growth factor (EGF) membrane receptors and promoted the anchorage-independent growth of nontransformed rodent cells. They differed from human EGF in their apparent molecular weights and soft-agar growth-stimulating activity. The urine from pregnant females contained TGF activities with apparent molecular weight(s) (relative) (M_r) of 10,000 and 17,000–20,000. In the case of a lung cancer patient, an additional major activity of approximately 30,000–35,000 M_r was found. All urine specimens examined also contained a "common" 8,000-M_r soft-agar growth-stimulating activity, which competed for binding to EGF membrane receptors and which was chromatographically separable from EGF (urogastrone). Thus urine may provide a convenient and readily available source for the biochemical characterization of these TGF-like activities, some of which may be clinically useful biologic markers for certain types of cancer.—JNCI 1982; 69:793–798.

Growth-promoting polypeptides have been found in the supernatants from cultures of virally transformed rodent cells (*1, 2*) and human tumor cells (*3*). Polypeptides with similar biologic activities have also been isolated directly from human tumor cells (*4*) and from early mouse embryo cells (*5*). In each case a family of heat- and acid-stable polypeptides of varying molecular weights has been identified that can reversibly stimulate the anchorage-independent growth of nontransformed rodent cells and has thus been designated TGF. For the most part, human TGF have been shown to compete with EGF for binding to EGF membrane receptors, although non-EGF-related peptides with soft-agar growth-promoting activity have also been identified (*3*). Nontransformed cells do not release detectable quantities of soft-agar growth-stimulatory factors into the culture supernatants (*1–3*). Since TGF are of low molecular weight and stable, it was thought that similar activities might also be detected in urine. We report here that the urine from pregnant and tumor-bearing humans does indeed contain TGF-like activities of varying molecular sizes.

MATERIALS AND METHODS

Urine extraction.—Normal urine pools consisted of early morning voided urine collected from 10 healthy laboratory workers ranging from 24 to 40 years of age. Pregnant donor urine pools were derived from mid- to late-term pregnant individuals of mixed child-bearing ages; the pools were collected during routine outpatient prenatal care examination. Fresh urine specimens were clarified by low-speed centrifugation, lyophilized to dryness, and extracted with the use of a modification of the procedure described by Roberts et al. (*4*) for isolation of TGF from tumor cells. The dry residue from approximately 2 liters of urine was resuspended in 375 ml of a solution containing 95% (vol/vol) ethanol, 7.5 ml concentrated HCl, 0.1 mg phenylmethylsulfonyl fluoride/ml, and 0.15 trypsin inhibitory units/ml of aprotinin from bovine lung. Distilled H_2O (185 ml) was then added, and the above suspension was extracted overnight at 4°C. Following centrifugation at 10,000×*g* for 1 hour, the supernatant was adjusted to pH 5.2 with concentrated ammonium hydroxide. One milliliter of 2 *M* ammonium acetate buffer (pH 5.2) was then added per 100 ml of extract. The resultant precipitate was discarded and the supernatant precipitated with four volumes of cold anhydrous ether and two volumes of cold ethanol (−20°C for 24 hr). The precipitate was collected by centrifugation, redissolved in 1 *M* acetic acid, and extensively dialyzed against 0.2 *M* acetic acid (Spectraphon tubing; mol wt cutoff, 3,500; Spectrum Medical Industries Inc., Los Angeles, Calif.). This extraction procedure generally yielded approximately 15–20 mg protein/liter of raw urine as determined by the method of Lowry et al. (*6*). The lyophilized protein was then resuspended in 6.5 ml of 1 *M* acetic acid, recentrifuged, and applied to a 2.5×100-cm Biogel P-100 column in 1 *M* acetic acid.

EGF binding assays.—EGF was isolated (*7*) and radiolabeled with ^{125}I (*8*) as previously described. Binding of ^{125}I-labeled EGF (*1, 2*) was measured on subconfluent monolayers of formaldehyde-fixed A431 cells in 16-mm tissue culture wells (Linbro No. 76-033-05). Competitions were initiated by the addition of 0.2 ml of binding buffer—DMEM containing 1 mg bovine serum albumin/ml and 50

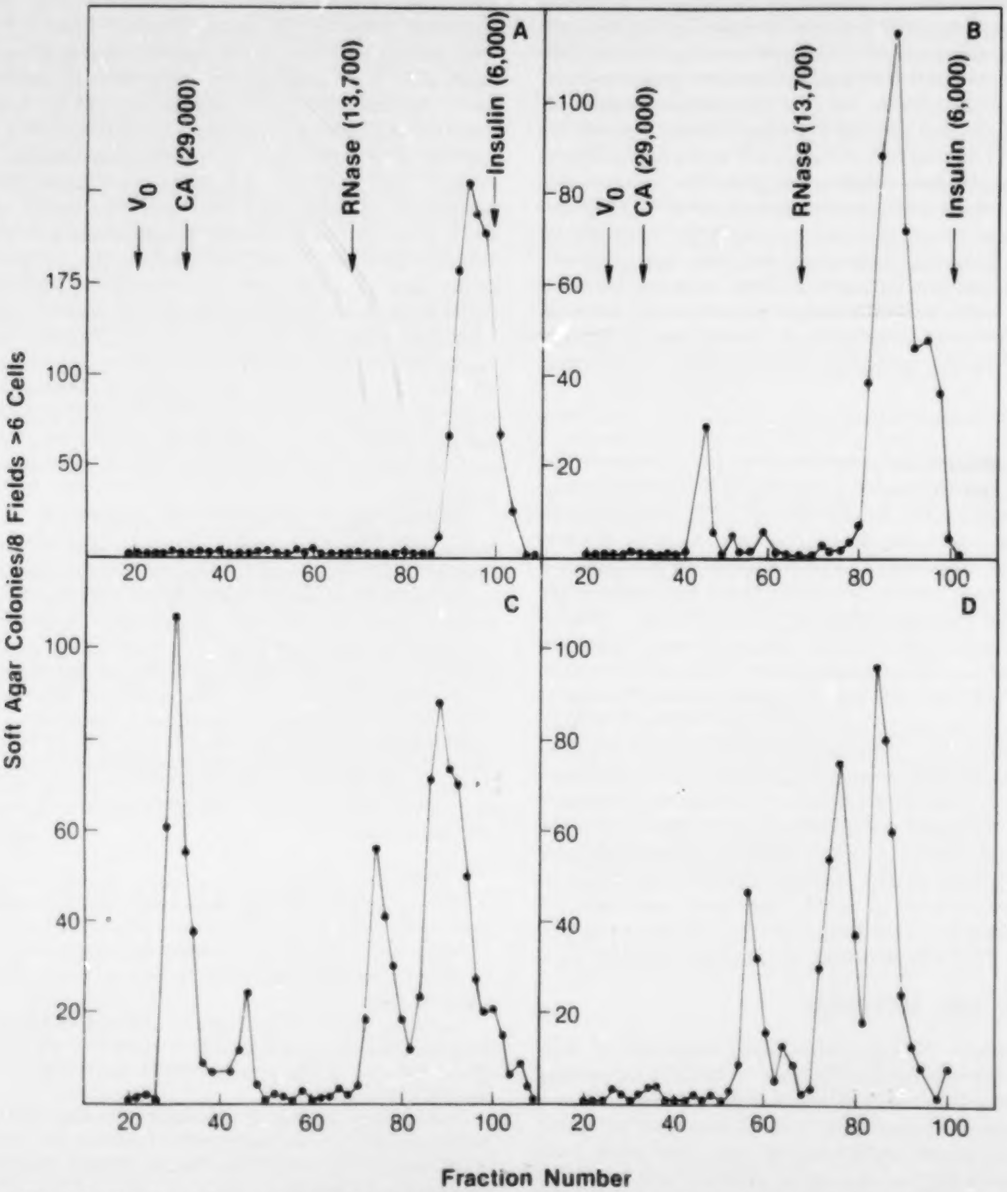
Bohn for his excellent technical assistance, Ms. Patricia Johnson for editing, and Ms. Virginia Frye for help in the preparation of this manuscript.

m*M* 2-[bis(2-hydroxyethyl)amino]ethanesulfonic acid adjusted to pH 6.8—containing 2 ng ^{125}I-labeled EGF/ml with or without an aliquot of the sample to be tested. After a 1-hour incubation at 22°C, the binding buffer was removed, culture wells were washed four times with binding buffer (1 ml), and the quantity of ^{125}I-labeled EGF specifically bound was determined.

Soft-agar colony assay.—The assay for colony growth in soft agar was as previously described (*1, 3*). A 2-ml base layer of 0.5% agar (Agar Noble; Difco Laboratories, Detroit, Mich.) in DMEM containing 10% calf serum was added to 60-mm Costar petri dishes. A 2-ml overlay of 0.3% agar containing the same medium–calf serum mixture, 2×10^3 NRK cells (clone 49F), and the sample to be tested was then added. The cells were incubated at 37°C in a humidified atmosphere of 5% CO$_2$ in air and refed after 7 days by addition



TEXT-FIGURE 1.—Biogel P-100 column chromatography of acid–ethanol-extracted human urine pools from A); normal males, 2 liters; B) normal females, 2 liters; C) untreated male SCCL patient, 0.4 liters; D) mid- to late-term pregnant females, 2 liters. Acid–ethanol-solubilized urinary peptides (15–20 mg protein/liter processed urine) were applied to a Biogel P-100 column (2.5×75 cm) equilibrated with 1 *M* acetic acid. Aliquots (1 ml) of each fraction (3.5 ml) were sterilized by lyophilization of 1-*M* acetic acid solutions in sterile tubes and assayed as described in "Materials and Methods" for the stimulation of NRK fibroblasts (clone 49F) to form progressively growing colonies in soft agar. Column markers included carbonic anhydrase, 29,000 daltons; RNase, 13,700 daltons; and insulin, 6,000 daltons. Mouse submaxillary gland EGF elutes from this column with the insulin marker.

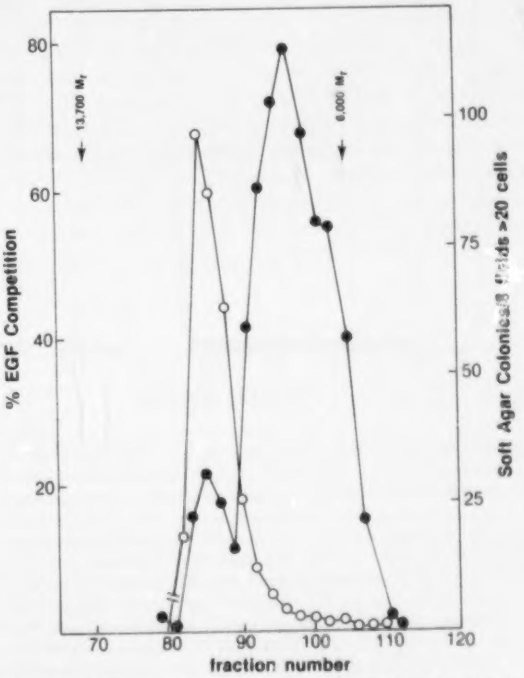
of 2 ml of 0.3% agar containing the appropriate supplements. Colonies were measured unfixed and unstained, and the number of colonies greater than 10 cells per 8 low-power random fields was scored after 14 days. NRK fibroblasts from clone 49F showed predominantly single cells after 14 days in these assays.

RESULTS

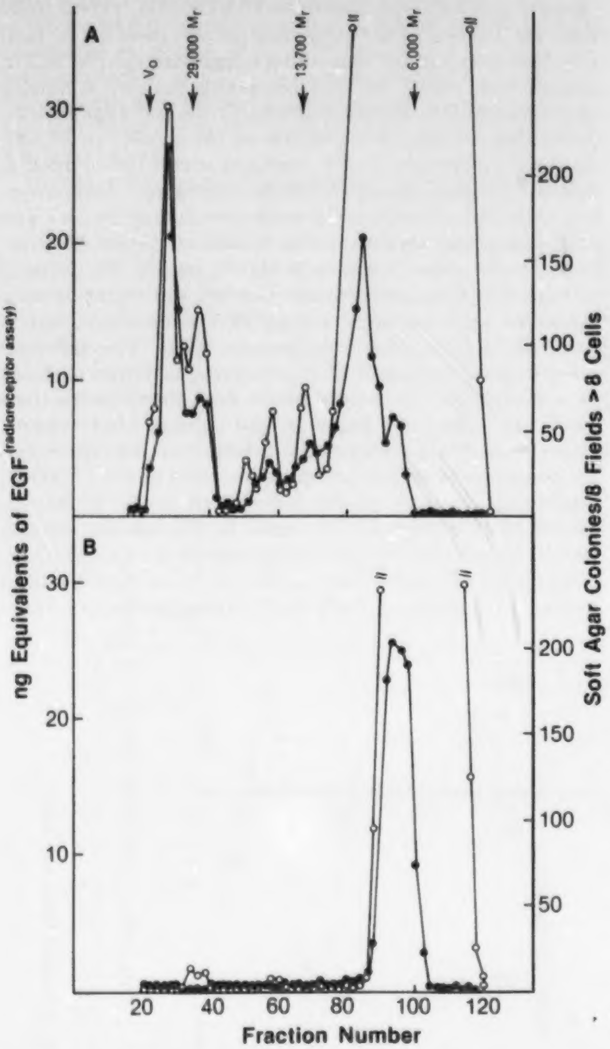
Acid–ethanol-extracted urine polypeptides were chromatographed on Biogel P-100 columns in 1 *M* acetic acid. Individual column fractions were then tested for their ability to stimulate the growth in soft agar of NRK fibroblasts. As shown in text-figure 1A, acid–ethanol-extracted urine derived from a pool of normal males contained peptides that supported anchorage-independent cell growth. Typical colonies were round and compact and usually contained more than 20–30 cells 3 days after being seeded in soft agar. This activity eluted from these columns with an apparent M_r of 8,000, slightly larger than that of EGF, which does not stimulate anchorage-independent cell growth and elutes under these conditions in fractions 95–105. In addition, for example, as shown in text-figure 2, the 8,000-M_r soft-agar growth-stimulating activity coeluted with EGF-competing activity (fractions 80–88), whereas the major EGF-competing activity eluting later (fractions 90–110) did not stimulate similar growth in soft agar. This minor EGF-competing component could only be detected in EGF binding assays with the use of dilutions of column fractions that minimized the excess concentration of EGF, which chromatographed in this low-molecular-weight region of the column.

The 8,000-M_r component eluted from high-pressure liquid chromatographic columns at solvent concentrations different than those of human EGF and will be described in detail elsewhere. No soft-agar growth-stimulatory activity from normal urine was detected in any column fractions corresponding to a higher molecular weight, and the A_{280} absorbance profile on these regions (fractions 20–80) was similar in all urine specimens examined, indicating no evidence of proteinuria. Similar activities were seen after chromatography of acid–ethanol-extracted urine derived from a pool of normal female donors (text-fig. 1B). In addition, a minor, although reproducible, soft-agar growth-promoting activity eluting in the region of approximately 25,000 M_r (fractions 42–48) was seen in normal female urine specimens. In contrast to the elution profile of soft-agar growth-promoting activity from the urine of normal males and females, several molecular species of TGF activity were found in acid–ethanol-extracted, pooled urine obtained from mid- to late-term pregnant females (text-fig. 1D). TGF activities corresponding to apparent M_r of 10,000 (fractions 70–80) and 17,000–20,000 (fractions 52–60) were seen in addition to the 8,000-M_r (fractions 85–95) activity common to all urine specimens examined thus far.

Since continuous cell lines derived from patients with SCCL have previously been shown in vitro to produce soft-agar growth-promoting factors (*9*), the urine of a 56-year-old, previously untreated, male patient with this type of lung cancer was also examined. In contrast to the TGF activities of pooled normal male and female controls, several higher molecular weight TGF activities were detected, including activities with apparent M_r of 30,000–35,000 (fractions 26–35) and 10,000 (fractions 70–80) (text-fig. 1, *panel C*). Moreover, when the column fractions of the SCCL patient were tested for EGF-competing activity according to previously described methods (*1*, *3*), the soft-agar growth-promoting activity, in particular in the 30,000- to 35,000-M_r region (fractions 25–35), coeluted with EGF-competing activity. A typical Biogel P-100 chromatograph demonstrating coelution of soft-agar growth-stimulating activity and EGF-competing activity in the 30,000- to 35,000-M_r (fractions 25–40) region is shown in text-figure 3A. The urine of this particular patient with alveolar cell soft tissue sarcoma contained approximately 250 ng EGF equivalents/liter of urine of the high-molecular-weight TGF. The soft-agar growth-stimulating and EGF-competing activities coeluted as a shoulder of the major protein peak found in fractions 20–25 and were not found in the column void volume. Other minor EGF-competing activities that also promoted anchorage-independent cell growth eluting in the 17,000- to 20,000-M_r (fractions 52–60) region and in the 10,000- to 12,000-M_r (fractions 65–75) region of the column are also seen in the urine of this previously untreated cancer patient. Text-figure 3B shows the profile of urine derived from normal individuals of both sexes. Again, the major EGF-



TEXT-FIGURE 2.—Biogel P-100 column chromatography of acid–ethanol-extracted urine from late-term pregnant females. Acid–ethanol-solubilized urinary peptides (30 mg protein) were applied to a Biogel P-100 column (20×70 cm) equilibrated with 1 *M* acetic acid. Aliquots of each fraction were lyophilized and tested at various dilutions for the EGF competition on receptor-rich A431 human carcinoma cells (*1*, *3*) and for the stimulation of NRK cells (clone 49F) to form colonies in soft agar as described in "Materials and Methods." The minor EGF-competing activity eluting in fractions 80–88 was resolved from EGF only when tested at dilutions >1:350. ●—●, ^{125}I-labeled EGF competition; ○—○, number of NRK colonies consisting of >20 cells in 8 random low-power fields.



TEXT-FIGURE 3.—Biogel P-100 column chromatography of acid–ethanol-extracted urine (200 ml) polypeptides (5.5 mg protein) from A) a patient with alveolar cell soft tissue sarcoma and B) solubilized urine (1 liter) polypeptides (25.7 mg) from a pool of healthy individuals. Aliquots (1 ml) of each fraction were lyophilized and tested for EGF competition on receptor-rich A431 human cells and for the stimulation of growth of NRK cells in soft agar as described in "Materials and Methods." Equivalents of EGF in nanograms were calculated by means of an EGF competition dilution curve constructed with the use of mouse submaxillary EGF as the standard. The column calibration is as described in the legend to text-fig. 1. ○—○, ^{125}I-labeled EGF competition; ●—●, number of NRK colonies consisting of >8 cells in 8 random low-power fields.

competing activity found in all urine specimens examined was human EGF (UR), which eluted in the region of the 6,000-M_r insulin marker. This activity did not support the growth in soft agar of NRK fibroblasts and competed in a radioimmune assay for human EGF.

The activity of the 10,000-M_r TGF component from the urine of pregnant donors and from a patient with SCCL was susceptible to treatment with trypsin or DTT (table 1),

TABLE 1.—*Stability of the 10,000-M_r TGF activity from the urine of an SCCL patient*

Treatment[a]	No. of soft-agar colonies/8 fields >10 cells

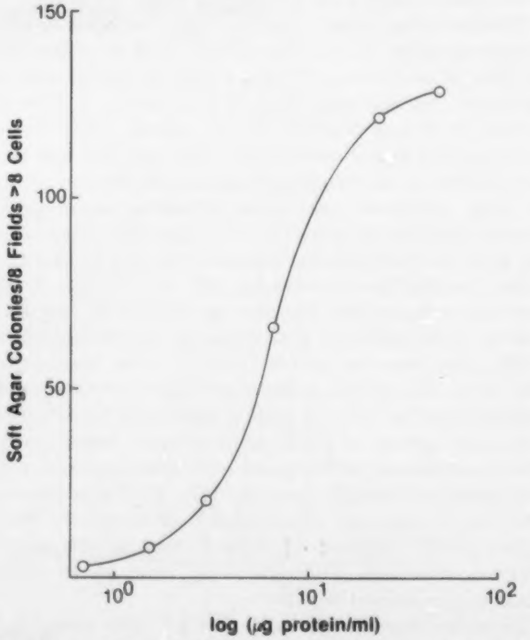
Trypsin	<1
DTT control	203
DTT	<5
Acetic acid control	188
Acetic acid	
4°C, 24 hr	200
22°C, 24 hr	210
37°C, 24 hr	205
Relyophilization (2×)	182

[a] The Biogel P-100 10,000-M_r TGF activity from urine derived from an SCCL patient was pooled, and equivalent aliquots were lyophilized and redissolved in 0.1 *M* NH_4HCO_3 (pH 7.8). A control solution and one containing 50 μg trypsin/ml were incubated at 37°C for 2 hr after which soybean trypsin inhibitor was added to each sample to give 100 μg/ml. For DTT treatment, a control solution and one containing 0.075 *M* DTT were incubated at 22°C for 2 hr followed by extensive dialysis against 0.2 *M* acetic acid. Each sample was then adjusted to 1 *M* in acetic acid and lyophilized. Acid stability studies were conducted in samples adjusted to 1 *M* in acetic acid prior to lyophilization. All samples were redissolved in binding buffer and assayed for soft-agar growth-promoting activity as previously described (*1, 3*).

as reported previously for sarcoma growth factor (*1*) and TGF from human tumor cells (*3, 4*). In addition, the activity was also heat-stable in 1 *M* acetic acid and was recovered after repeated lyophilizations. Both the EGF-competing and soft-agar growth-stimulating activity for the urine-derived



TEXT-FIGURE 4.—Soft-agar dilution assay of the 30,000- to 35,000-M_r TGF activity isolated from the urine of a patient with soft tissue sarcoma. Fractions corresponding to the 30,000- to 35,000-M_r region (fractions 28–30) from a Biogel P-100 column (*see* text-fig. 3A) were pooled, lyophilized, and tested at the protein concentration indicated above for stimulation of NRK cells to form progressively growing colonies in soft agar as previously described.

TABLE 2.—*TGF activity*

Urine source[a]	10,000 M_r	17,000–20,000 M_r	30,000 M_r
Normal male	−		−
Normal female	−	−	−
Pregnant female[b]	+	+	−
SCCL patient[c]	+	−	+

[a] With the exception of the SCCL patient, all urine samples represent a pool derived from multiple donors.

[b] Pregnant donors ranged from second to third trimester in their pregnancy.

[c] Previously untreated patient with disseminated disease.

30,000- to 35,000-M_r TGF activity from previously untreated cancer patients also exhibited a typical dose-response curve and, as with the TGF isolated from cell culture fluids, the high-molecular-weight urine TGF have both transforming and EGF-competing activities. The number of soft-agar colonies formed was proportional to the amount of protein added and, as shown in text-figure 4, approximately 100 soft-agar colonies were stimulated to grow by the addition of 10 μg input protein of TGF activity (30,000- to 35,000-M_r region) from a patient with soft tissue sarcoma. These data indicate a functional similarity between TGF-like activities found in urine from tumor-bearing humans and those identified in conditioned medium from tumor cell cultures.

DISCUSSION

The experiments described above demonstrate that the acid-ethanol extraction procedure previously used to isolate TGF from tumor cells (*4*) can be used to identify similar factors in human urine. The family of TGF-like polypeptides isolated from urine exhibited many of the biologic and biochemical characteristics of the TGF isolated from cell culture supernatants derived from mouse (*1*), rat (*2*), and human transformed cells (*3*). In addition to competing for EGF membrane receptors and stimulating anchorage-independent cell growth, these urinary peptides further resemble TGF in that they were also acid- and heat-stable and required disulfide bonds for activity. In contrast to human EGF, which did not stimulate the growth of large colonies in soft agar, the urinary TGF-like activities eluted from acidified Biogel columns with higher apparent molecular weights. The relatedness of the "common" urinary 8,000-M_r TGF-like activity to TGF isolated from tumor cell cultures remains to be determined. The possibility that this activity represents a form of UR with modified biologic activity must also be considered.

As shown in table 2, the 10,000-M_r TGF activity was found in the urine of mid- to late-term pregnant females and a patient with SCCL. These activities were not detected in urine pools derived from normal males and nonpregnant females. The 17,000- to 20,000-M_r components, however, appeared to be restricted to the urine of pregnant females. In this regard the exact source of TGF activity in the urine of pregnant females has yet to be established, but experiments with mice have identified TGF activity at 10,000 and 17,000–20,000 M_r in the 12- to 14-day mouse embryo (*5*), which suggests that the human fetus may also be capable of producing such factors.

In addition to having the 10,000-M_r factor, urine derived from previously untreated cancer patients (18 of 22) with a variety of carcinomas, including lung, breast, and colon, contained a major TGF activity with an apparent M_r of 30,000–35,000 (Sherwin SA, Twardzik DR, Bohn W, Cockley K, Todaro GJ: Manuscript submitted). This activity was not detected in the urine from an equal number of age- and sex-matched controls. Since SCCL cells in vitro have been shown to produce soft-agar growth-stimulating factors (*9*), it can also be postulated that the unusually high-molecular-weight TGF activity in the urine of the patient with SCCL is derived from his tumor cells. Furthermore, high-molecular-weight TGF activities have recently been detected (*10*) in surgically removed human tumors, including adenocarcinomas of the breast, colon, and ovary. Inasmuch as TGF are secreted into tumor cell culture fluids, we propose that these tumor cell products or TGF are released from tumor cells in vivo and subsequently cleared into the urine. We must, however, also entertain the possibility that this tumor-"associated" activity may be a host response to tumor burden. The relationship of the high-molecular-weight (30,000–35,000 M_r) TGF activity found in the urine of previously untreated cancer patients to a high-molecular-weight form of human EGF also found in urine (*11, 12*) is presently being examined. The detection of peptides with diverse biologic effects in the urine is not a novel observation because, for example, peptides that stimulate capillary endothelial cell migration have been found in the urine of patients with bladder tumors (*13*). What is interesting, nevertheless, is that this family of growth-stimulating peptides found in the urine under different physiologic states does exhibit a biologic activity; i.e., it promotes the reversion of nontransformed cells to the transformed phenotype, and high-molecular-weight forms of these growth factors may prove to be useful biologic markers in certain types of cancers.

Selective Cytotoxicity of a Ricin A-Chain–Anti-Carcinoembryonic Antigen Antibody Conjugate for a Human Colon Adenocarcinoma Cell Line[1,2]

Thomas W. Griffin,[3,4] Linda R. Haynes,[3] *and* Julie A. DeMartino[3]

ABSTRACT—Ricin A-chain, the toxic subunit of the potent plant toxin ricin, has been isolated by affinity chromatography and conjugated via a disulfide linkage to affinity-purified goat anti-carcinoembryonic antigen (CEA) antibody. Such conjugates retained the integrity of their antibody-combining site, as demonstrated by the ability to displace ^{125}I-labeled anti-CEA antibody bound to CEA-positive cell lines. In addition, such conjugates retained A-chain activity, producing inhibition of [^{14}C]leucine incorporation into a CEA-negative G-361 human melanoma cell line at concentrations similar to those of unconjugated A-chain. However, these conjugates were 40 times as potent in the inhibition of [^{14}C]leucine incorporation in the CEA-bearing WiDr human adenocarcinoma cell line as A-chain alone or as an unreacted mixture of A-chain and specific antibody. Such toxicity could be blocked by preincubation of the conjugate with fluid-phase CEA. Complete inhibition of [^{14}C]leucine incorporation as well as inhibition of cellular proliferation by the conjugate was seen at 50 n*M* concentration. Conjugates that combine the determinant specificity of an antibody with the toxicity of ricin A-chain may show promise as selective cytotoxins for cells bearing CEA.—JNCI 1982; 69:799–805.

The use of presently available antitumor agents is limited to a major extent by their nonspecific cytotoxic effect on normal cells. The concept of increasing the selectivity of antitumor agents by linkage of "antitumor" antibodies dates back nearly a century (*1*) and has been the subject of intense and imaginative investigation for the past 3 decades. These investigations have been the subject of several recent reviews (*2–4*). Although the present understanding of the genetic heterogeneity and clonal evolution of human tumor cell populations makes "magic bullet" therapy problematic, nevertheless, a combination of the selectivity of antibody with the lethal effects of toxins offers the promise of antitumor therapy with increased selectivity. Although early results gave only marginal specificity for target cells, more recent efforts that utilized improved methods of chemical coupling have demonstrated greater success. Furthermore, two recent developments have caused reassessment of the use of such "immunotoxins." The first development is the prospective availability of hybridoma-derived homogenous antibodies, with defined specificity, avidity, and class, against tumor-related antigens (*5*). The second advance is a greatly improved understanding of the structure and mechanism of action of the potent toxic proteins ricin, abrin, diphtheria toxin, and others (*6–8*).

Previous investigators have suggested that antibody delivery systems for cytotoxins are most successful when they utilize extremely toxic substances (*9–11*). The toxic proteins we used satisfy such a requirement, in that their toxic moieties act enzymatically, rather than stoichiometrically, to inhibit protein synthesis (*6–9*). Thus only a few molecules of these effector subunits are capable of producing cytotoxicity if entry is gained to the cytoplasm. However, utilization of the complete toxin incurs the risk of nonspecific toxicity. To circumvent this difficulty, we, (*12*) and other investigators (*13–17*) have explored the selective toxicity of conjugates of a specific antibody and the toxic subunit of ricin. Ricin, a potent protein inhibitor derived from the castor bean, has proved exceptionally adaptable to this approach, in that the toxin molecule shows segregation of biologic function into *a*) a binding (or B) chain that adheres to galactose moieties on the cell surface, and *b*) an activity (or A) chain that enzymatically inactivates ribosomes (*8*). These investigations have shown that it is possible to substitute specific antibody or antibody fragments as fraudulent B-chains, thereby producing conjugates of high cytotoxic potential, specific for cells that bear the appropriate antigen.

The present report extends these observations to conjugates constructed with antibodies directed against the oncofetal protein CEA. This operationally defined antigen describes a family of glycoproteins found on the surfaces of a variety of human cancers (*18*), and this family may be an appropriate target for clinically relevant immunotoxins.

MATERIALS AND METHODS

Cell lines.—The human adenocarcinoma cell line WiDr and human melanoma cell line G-361 were both obtained from the American Type Culture Collection, Rockville, Md. GM 316 fibroblasts were obtained from the Institute for Medical Research, Camden, N.J. The human adenocarcinoma cell line HT-29 was donated by Dr. J. Fogh, Sloan-Kettering Institute for Cancer Research, Rye, N.Y. Both adenocarcinoma cell lines have been shown to produce CEA in culture (*19–21*). HT-29 produces relatively small amounts of CEA in culture, whereas WiDr produces small to mod-

erate amounts compared to amounts produced by other adenocarcinoma cell lines (*22*).

Antibody and free antigen.—High-titer, affinity-purified goat anti-CEA antibody (lot #RK-1) was a gift of Dr. H. J. Hansen, Hoffman-LaRoche, Inc., Nutley, N.J. Soluble-phase CEA (1 mg/ml in PBS) was also obtained from Dr. Hansen. ^{125}I-radiolabeled anti-CEA antibody was donated by Dr. Steven Rose, Abbott Laboratories, North Chicago, Ill. Control antibody (affinity-purified goat anti-human IgG) was obtained from Kirkegaard & Perry Laboratories, Gaithersburg, Md.

Isolation of ricin A-chain.—Ricin A-chain was isolated from the parent toxin (Sigma Chemical Co., St. Louis, Mo.; EY Laboratories, San Mateo, Calif.) by an adaptation of a previously described method (*23*). The toxin was reduced by the addition of 2-mercaptoethanol to a final concentration of 5%, incubated for 12 hours at 23°C, and centrifuged at 3,000 rpm for 15 minutes. The supernatant was then applied to a column of lactose-substituted agarose (Selectin 12; Pierce Chemical Co., Rockford, Ill.). The isolated A-chain was eluted with PBS that contained 0.1% 2-mercaptoethanol. Further traces of contaminating ricin and B-chain were then removed by passage over a Sepharose 4B column pretreated with 1 *N* acetic acid for 24 hours and washed extensively with elution buffer (*24*). After repeated elution of the A-chain, the peak tubes were pooled, dialyzed against PBS for removal of residual 2-mercaptoethanol, and concentrated by ultrafiltration (PM10 membrane; Amicon Corp., Lexington, Mass.). The resulting product was further purified by passage over a Sephadex G-25 column. The homogeneity of the A-chain prepared in this manner was assessed by SDS-PAGE by a previously described method (fig. 1.) (*25, 26*). The integrity of A-chain protein inhibition was assessed in a rabbit reticulocyte lysate system (Bethesda Research Laboratories, Inc., Gaithersburg, Md.). Successfully purified A-chain demonstrated an ID_{50} of [^{14}C]leucine incorporation of $1\text{-}5\times10^{-7}$ *M* in WiDr cells in the system described above, compared to the ID_{50} of intact ricin of 2×10^{-10} *M*. Additional ricin A-chain was obtained commercially from EY Laboratories.

Synthesis of ricin A-chain–antibody conjugates.—Affinity-purified antibody, at a concentration of 2.5 mg/ml, was dialyzed against PBS for 24 hours and then reacted with a 25-fold molar excess of the bifunctional coupling reagent *N*-succinimidyl-3-(2-pyridyldithio)propionate (Pharmacia, Fine Chemicals, Piscataway, N.J.) (*27*). Reaction continued at 23°C for 30 minutes, after which time reaction products were again dialyzed against PBS for an additional 24 hours. The resulting protein was then reacted with a two times molar excess of ricin A-chain. The progress of the reaction was monitored by release of pyridine-2-thione (increased absorbance at 343 nm). Reaction products were then separated on a molecular sizing column (Sephadex G-100). Progress of the reaction was confirmed by SDS-PAGE (fig. 1.).

^{125}I-labeled anti-CEA antibody binding assay.—To measure specific binding of ^{125}I-labeled anti-CEA antibody by the various cell lines, we performed competitive binding experiments with radioiodinated anti-CEA antibody, unreacted antibody, and conjugate in this manner: 1 ml of the designated cell line (at 4×10^4 cells/ml) was spun to a firm pellet (2,000 rpm for 10 min). The supernatant was removed, and ^{125}I-labeled anti-CEA antibody (10^5 cpm/0.05 ml) was added to the pellet. The cells were then incubated at 23°C for 30 minutes, washed twice with 1 ml of PBS, and then pelleted and counted. The absolute number of counts bound was obtained by the subtraction of counts in tubes containing radiolabeled antibody alone from counts in tubes containing label and cells. In experiments that demonstrated the integrity of the antibody combining site, cells were preincubated for 30 minutes at 23°C with unlabeled anti-CFE antibody or conjugate in the designated amount and then treated in the above manner.

Assay of protein inhibition.—Confluent WiDr cells were removed with a T-75 flask with 0.25% trypsin and 0.02% EDTA. The cells were then suspended in leucine-free medium (MEM with 10% FCS and 1% antibiotics) and seeded into microtiter wells (2×10^4 cells/well). The cells were incubated (after appropriate additions of conjugate, ricin, ricin A-chain, or unconjugated antibody to achieve the specified levels) for 16 hours at 37°C in 5% CO_2, treated with a 3-hour pulse of [^{14}C]leucine (New England Nuclear Corp., Boston, Mass.), and harvested onto filter disks with a Mash II cell harvester. Incorporation of radioactivity into the cells was measured by scintillation counting after extensive washing on a glass fiber filter.

Reversal of toxicity by free CEA.—Specific anti-CEA conjugate (2×10^{-7} *M*) was incubated for 1 hour with free CEA (2×10^{-7} *M*) and then added to WiDr cells to a final conjugate concentration of 1×10^{-8} *M*. Inhibition of [^{14}C]leucine incorporation was assayed in the manner described and was compared to that of unreacted conjugate, free antigen, or controls.

Reversal of toxicity by free antibody.—Confluent WiDr cells were removed from a T-75 flask with 0.25% trypsin in 0.02% EDTA. The cells were resuspended in leucine-free medium (EMEM, 10% FCS, and antibiotics) at a concentration of 10^5 cells/ml. The cells were then centrifuged (2,000 rpm for 5 min) to a pellet, and the supernatant was removed.

Unreacted anti-CEA antibody or nonspecific antibody was added to the pellet at a concentration of 2.0×10^{-5} *M* (2-log excess over conjugate). Similarly handled cells were treated with an equal volume of PBS alone. The cells were then incubated at 23°C for 1 hour, and conjugate (1×10^{-7} *M*) was added to PBS and antibody-treated cells. After a subsequent 1-hour incubation at 23°C, the cells were washed with medium and plated into microtiter wells. [^{14}C]leucine incorporation was then determined in the manner described above.

RESULTS

PAGE of Ricin A-Chain–Anti-CEA Antibody Conjugates

Figure 1 presents PAGE of unreacted antibody, free A-chain, conjugate, and conjugate after reduction. These dual bands of isolated A-chain (fig. 1: A, B, I, J) were seen in both A-chain preparations obtained from the parent toxin, by the above-cited method, and in that obtained commercially. The appearance of homologous A-chains of these

TABLE 1.—*Binding of ^{125}I-labeled anti-CEA antibody by cells in culture*

Culture	cpm per 2×10^4 cells ± SD
GM 316 fibroblasts	159±12
G-361 melanoma	224±12
HT-29 adenocarcinoma	1,819±232
WiDr adenocarcinoma	3,201±284

molecular masses (30,000 and 33,000 daltons) following reduction of the parent toxin has been previously described (*28*). The affinity-isolated antibody (G) is a broad band at a molecular mass of approximately 150,000 daltons, whereas the conjugate preparation (C and E) shows an increase in the molecular mass over that of antibody alone, suggesting the addition of A-chain to the antibody. Reappearance of the free A-chain bands following DTT treatment of the conjugate (D and F) confirms successful synthesis of the conjugate.

Binding of Anti-CEA Antibody–Ricin A-Chain Conjugates by CEA-Positive Cell Lines

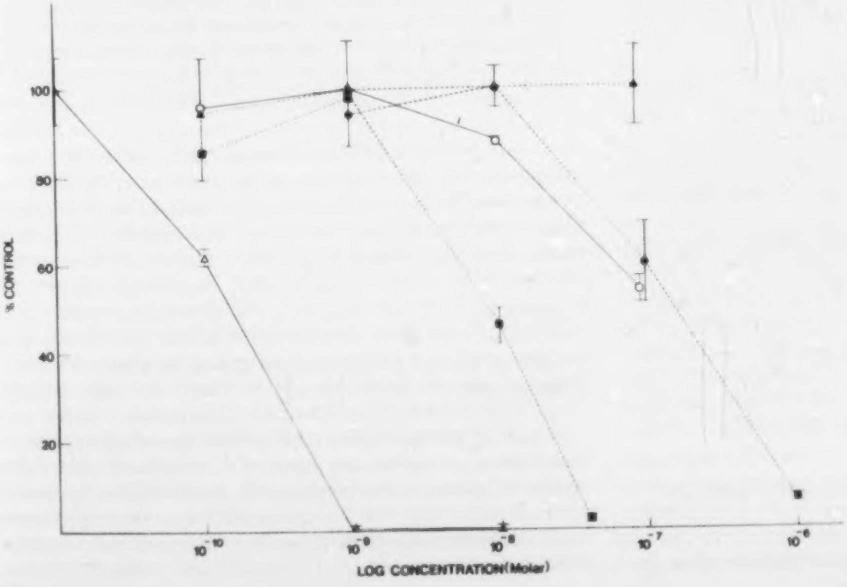
HT-29 adenocarcinoma cells produce small amounts of CEA during growth in vitro and have been shown to bind anti-CEA antibody, both by immunofluorescence and by the binding of radiolabeled antibody (*29, 30*). WiDr, a recently characterized cell line, produces a moderate amount of CEA (118 ng/10^6 cells in 10 days: American Type Culture Collection Information Sheet) compared to that produced by other colorectal adenocarcinoma cell lines in vitro (*22*).

Table 1 presents the degree of binding of ^{125}I-labeled anti-CEA antibody by the fibroblast line GM 316, the human melanoma G-361, and the two adenocarcinoma cell lines HT-29 and WiDr. The binding of ^{125}I-labeled anti-CEA antibody by the nonadenocarcinoma cells lines was similar to nonspecific binding to the adenocarcinoma cells, as defined by binding of radiolabeled antibody not displaceable by preincubation with 10^{-6} *M* unlabeled specific antibody. Thus by this method of analysis, these cell lines express little or no CEA on their cell membrane. In contrast, the adenocarcinoma cell lines showed specific binding of ^{125}I-labeled anti-CEA antibody. The moderate CEA producer WiDr bound more radiolabeled antibody than the low CEA producer HT-29. Similar in vitro binding of radiolabeled anti-CEA antibody by the HT-29 cell line has been previously described by Tompkins and colleagues (*30*).

TABLE 2.—*Inhibition of binding of ^{125}I-labeled CEA antibody by conjugate and unreacted antibody*

Cell line	Concentration, *M*	cpm per 2×10^4 cells	Inhibition of binding, %
WiDr			
Control		2,686	
Conjugate	9×10^{-7}	1,236	54
	9×10^{-8}	2,112	21
Antibody	9×10^{-7}	863	67
	9×10^{-8}	1,581	41
HT-29 adenocarcinoma			
Control		2,172	
Conjugate	9×10^{-7}	691	68
	9×10^{-8}	2,098	3
Antibody	9×10^{-7}	680	68
	9×10^{-8}	1,856	14

To demonstrate retention of antigen-binding activity of the anti-CEA–ricin A-chain conjugates, we compared the ability of these conjugates to prevent binding of ^{125}I-labeled anti-CEA antibody to that of unreacted antibody (table 2). This displacement was concentration related, with 50% of bound counts displaced by pretreatment with a concentration of 5–7×10^{-7} *M* conjugates and 3–5×10^{-7} *M* unreacted antibody in the two adenocarcinoma cell lines. Thus the conjugate showed comparable or slightly reduced reactivity with cell surface CEA as free antibody, thereby



TEXT-FIGURE 1.—Inhibition of [^{14}C]leucine incorporation in WiDr cells by ricin, ricin A-chain, specific conjugate, specific antibody, or a noncovalent mixture of ricin A-chain and antibody. Cells (2×10^4/microtiter well) were incubated in leucine-free medium with 5% FCS at 37°C in 5% CO_2 for 16 hr after appropriate additions of the above compounds at the designated concentrations. At 16 hr, the cells were treated with [^{14}C]leucine (0.2 μCi/well) for 3 hr and gathered onto filter disks with a Mash II cell harvester, and the radioactivity incorporated was counted. *Each data point* represents the mean of six measurements. *Vertical bars* represent the standard deviation. ●—●, ricin A-chain; ○—○, anti-CEA antibody + A-chain; ▲—▲, anti-CEA antibody; △—△, ricin; ■—■, anti-CEA–ricin A-chain conjugate.

confirming the integrity of the antigen-combining site in the conjugate. The slightly reduced reactivity of the conjugate may be related to steric interference by A-chain with antigen–antibody interaction.

Inhibition of $[^{14}C]$Leucine Incorporation in Human Adenocarcinoma Cell Lines by Ricin A-Chain–Anti-CEA Antibody Conjugates

Dose-response curves of inhibition of $[^{14}C]$leucine incorporation in WiDr CEA-positive cells are presented in text-figure 1. The ID$_{50}$ for intact ricin in this system was 2×10^{-10} *M*. The ID$_{50}$ levels for whole ricin in the presence of serum proteins, which inhibit its binding, may be overestimates. Conjugates prepared in the above manner had an ID$_{50}$ of 8×10^{-9} *M* or approximately, 2.5% that of the native toxin. Levels of 5×10^{-8} *M* completely inhibited $[^{14}C]$leucine incorporation. The A-chain itself, or mixed with unconjugated antibody, had an ID$_{50}$ of 3×10^{-7} *M* or 0.1% of the parent toxin. Free antibody alone gave no inhibition of protein synthesis in this system. The conjugate was, therefore, 40 times more effective than free A-chain in producing an inhibition of protein synthesis in this system. In contrast, the conjugate was not more toxic than free A-chain in the melanoma cell line G-361, which bears no CEA.

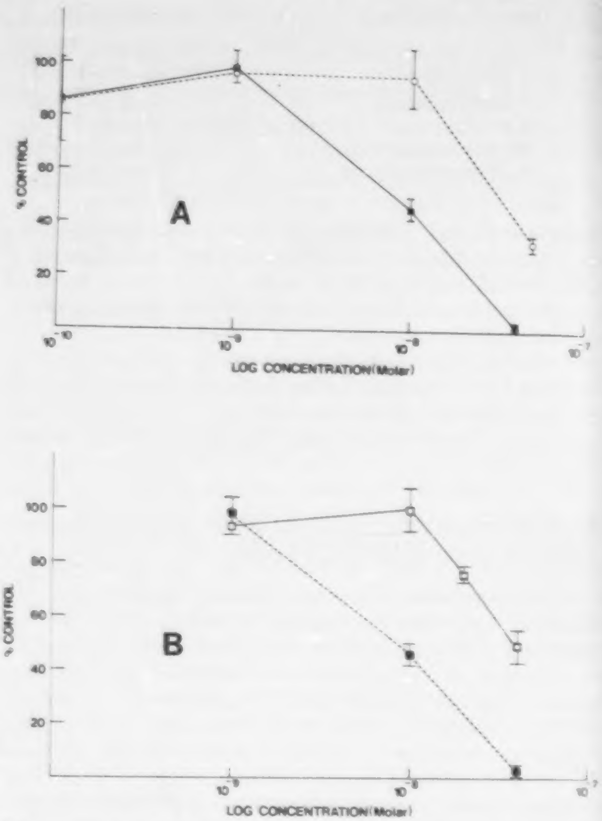
To determine whether the inhibition of $[^{14}C]$leucine incorporation was associated with cytotoxic effect, we examined the effect of specific conjugate, free A-chain, and a noncovalent mixture of A-chain and antibody on adenocarcinoma proliferation in vitro. WiDr cells were seeded as above with the exception that complete medium (EMEM with leucine, 10% FCS, and 1% antibiotics) rather than leucine-free medium was used, and daily cell enumerations were obtained by a Coulter counter. The number of untreated cells increased five times over 5 days. At a level of 5×10^{-8} *M* conjugate, 50% inhibition of cellular proliferation at 5 days was seen. Similar degrees of inhibition required levels of 1×10^{-6} *M* A-chain or 1×10^{-6} *M* A-chain plus antibody. Thus the conjugate demonstrated the capacity to function as a potent cytotoxin against cells bearing the appropriate antigen.

Text-figure 2A compares protein inhibition in WiDr versus the control cell line human melanoma G-361. G-361 cells showed similar sensitivity to protein synthesis inhibition by ricin and ricin A-chain as WiDr in that system. Again, the specificity of conjugate effect was approximately eightfold at the ID$_{50}$ concentration.

In text-figure 2B the toxicity of specific anti-CEA conjugate is compared with that of a conjugate prepared with nonspecific antibody (goat anti-human IgG, affinity purified). This nonspecific antibody was more toxic than free A-chain (three times at the ID$_{50}$) but still eightfold less toxic than specific conjugates at the ID$_{50}$ level. In contrast, the nonspecific conjugate showed equivalent toxicity (ID$_{50}\approx1\times10^{-7}$ *M*) to both the CEA-bearing and CEA-negative cell lines.

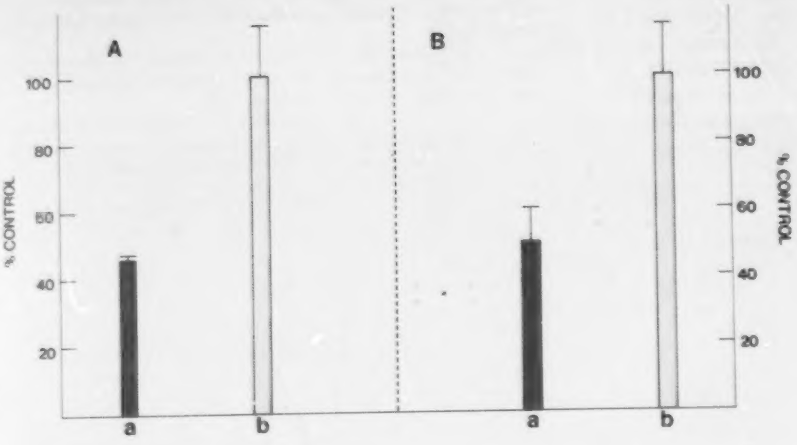
Reversal of Conjugate Toxicity by Specific Antigen and Specific Antibody

To demonstrate that the increased toxicity of the ricin A-chain–antibody conjugate was mediated by the CEA combining site of the antibody moiety of the conjugate, we showed reversal of cytotoxic effect with both fluid-phase antigen and excess free antibody. Text-figure 3A demonstrates complete reversal of the inhibitory action of the conjugates by preincubation with equimolar amount of fluid-phase antigen for 1 hour. No precipitation occurred during this incubation. Simultaneous addition of fluid-phase antigen produced no reversal of cytotoxic effect. Preincubation of the nonspecific conjugate with fluid-phase antigen under identical conditions had no effect on its toxicity.



TEXT-FIGURE 2.—Specificity of conjugate action: A) Protein inhibition in the ■, specific (WiDr) cell line vs. a control cell line, ○, human melanoma G-361. The G-361 cell line bound little or no radiolabeled anti-CEA antibody and showed equivalent sensitivity to WiDr to the inhibition of $[^{14}C]$leucine incorporation by ricin and ricin A-chain. Dose-response curves were generated in the manner described in the legend to text-fig. 1. B) Comparison between the inhibition of $[^{14}C]$leucine incorporation by ■, specific (affinity-isolated goat anti-CEA antiserum) conjugate, vs. □, control (affinity-purified goat anti-human IgG antiserum) conjugate in WiDr colorectal cells. The same degree of molar substitution of ricin A-chain/mole antibody was observed in both preparations. Dose-response curves were generated as described in the legend to text-fig. 1.

Similar reversal of conjugate inhibitory effect was demonstrated with excess free antibody (text-fig. 3B). A 2-log antibody excess pretreatment was required for complete reversal, with lesser effects seen with 1-log excess and equimolar amounts. Nonspecific antibody pretreatment had no effect on conjugate action.



TEXT-FIGURE 3.—Blockage of inhibitory action of conjugate by preincubation with free antigen or antibody. A) The inhibitory action of the (a) specific conjugate can be blocked by preincubation of the conjugate with (b), equimolar amounts of fluid-phase antigen. The assay for protein inhibition was performed as described, with conjugate CEA reaction mixture at a concentration of 1×10^{-8} *M*. B) The inhibition of [^{14}C]leucine incorporation by (a), specific conjugate can also be reversed by pretreatment with (b), specific (anti-CEA) antibody. In these experiments the WiDr adenocarcinoma cells were incubated for 1 hr at 23°C with a 2-log excess (10^{-5} *M*) of anti-CEA antibody, before a 1 hr incubation with 10^{-7} *M* conjugate. The cells were washed twice with PBS before being resuspended in leucine-free medium with 5% FCS, and seeded into microtiter wells at a concentration of 2×10^{4} cells/well. The remainder of the experiments was conducted in the manner described in the legend to text-fig. 1.

DISCUSSION

The demonstration that specific antibody or antibody fragments can serve as alternate binding units for the toxic A-chains of ricin and diphtheria toxin (*12–16*) and impart antigen-dictated selective cytotoxicity to these conjugates has rekindled interest in such immunotoxins as selective antitumor agents. Most attempts to date have focused on lymphocyte-differentiation antigens (*16*), surface IgG on B-lymphocytes (*12, 13*), or artificially introduced antigens (*15*), except one study that described the use of a monoclonal antibody directed against an antigen that was reported specific for colorectal adenocarcinoma (*14*).

CEA was first described by Gold and Freedman (*31*) in 1965 as an antigen associated with embryonic and neoplastic gastrointestinal tissues. A radioimmunoassay for CEA was reported in 1969. The presence of detectable quantities of CEA in adult serum was originally thought to be specific for the presence of cancer, but recent evidence indicates that CEA may be elevated in many benign conditions as well (*18*). In addition, CEA levels are commonly elevated in many cancers of nondigestive tract origin (*32*). CEA is operationally defined by reagents similar to those originally used by Gold and Freedman (*31*) and is immunochemically complex. Evidence now suggests that CEA describes a family of related glycoproteins, with a wide range of molecular weights and carbohydrate content (*33*). Polar redistribution of CEA expressed on the surfaces of human intestinal carcinoma cells in culture induced by specific antibody has been described (*29*).

The inhomogeneity of the CEA, its shedding by malignant cells, and its wide distribution may limit the usefulness of such conjugates as described here. However, an extensive literature has documented the successful in vivo tumor localization of radiolabeled anti-CEA antisera in both animal and clinical models (*34*) and possible therapeutic utility of such conjugates (*35*). Therefore, despite the limitations of this system noted above, CEA remains an attractive antigenic "target" for immunotoxins.

Previous investigators have described CEA antiserum as a carrier of cytotoxins. Shearer et al. (*36*) reported specific cytotoxicity of glucose oxidase–anti-CEA antisera for human colon carcinoma cells (HT-29). This system required subsequent treatment with glucose, iodide, and lactoperioxidase for production of specific iodination of cell membranes, and, therefore, is much more cumbersome than the system described here. Belles-Isles and Page (*37*) have described selective cytotoxicity of daunomycin–anti-CEA conjugates for a human colon carcinoma cell line. Similarly, Johnson et al. (*38*) have recently described a conjugate of sheep anti-CEA immunoglobulin and the anticancer drug vindesine, which was cytotoxic for human cancer cells in vitro. The optimal cytotoxin for antibody conjugation will require further study, but the relative lack of cytotoxicity of isolated ricin A-chain makes it an attractive candidate.
